PHILOSOPHICAL AND MATHEMATICAL
DICTIONARY.

VOL. I.

PRINTED BY S. HAMILTON,
Weybridge, Surrey.

PHILOSOPHICAL AND MATHEMATICAL
DICTIONARY:

CONTAINING

AN EXPLANATION OF THE TERMS, AND AN ACCOUNT OF THE SEVERAL SUBJECTS,

COMPRISED UNDER THE HEADS

MATHEMATICS, ASTRONOMY, AND PHILOSOPHY
BOTH NATURAL AND EXPERIMENTAL;

WITH AN

HISTORICAL ACCOUNT OF THE RISE, PROGRESS, AND PRESENT STATE OF THESE SCIENCES;

BOSTON COLLEGE LIBRARY
CHESTNUT HILL, MASS.

MEMOIRS OF THE LIVES AND WRITINGS OF THE MOST EMINENT AUTHORS,
BOTH ANCIENT AND MODERN,

WHO BY THEIR DISCOVERIES OR IMPROVEMENTS HAVE CONTRIBUTED TO THE ADVANCEMENT OF THEM.

BY CHARLES HUTTON, LL.D.

FELLOW OF THE ROYAL SOCIETIES OF LONDON AND EDINBURGH, AND OF THE PHILOSOPHICAL SOCIETIES OF HAARLEM
AND AMERICA; AND EMERITUS PROFESSOR OF MATHEMATICS IN THE ROYAL
MILITARY ACADEMY, WOOLWICH.

IN TWO VOLUMES:

WITH MANY CUTS AND COPPER-PLATES.

A NEW EDITION.

WITH NUMEROUS ADDITIONS AND IMPROVEMENTS.

V O L. I.

L O N D O N :

PRINTED FOR THE AUTHOR;

F. C. AND J. RIVINGTON ; J. CUTHELL ; LAW AND WHITTAKER ; LONGMAN, HURST, REES, ORME, AND BROWN ; CADELL AND DAVIES ; J. MAWMAN ; BLACK, PARRY, AND CO ; BALDWIN, CRADOCK AND JOY ; J. BOOKER ; G. AND S. ROBINSON ; T. HAMILTON ; WALKER AND EDWARDS ; JOHN ROBINSON ; B. REYNOLDS ; AND SIMPKIN AND MARSHALL.

1815.

P R E F A C E.

AMONG the Dictionaries of Arts and Sciences which have been published, of late years, in various parts of Europe, it is matter of surprise that Philosophy and Mathematics should have been so far overlooked as not to be thought worthy of a separate Treatise, in this form. These sciences constitute a large portion of the present stock of human knowledge, and have been usually considered as possessing a degree of importance to which few others are entitled; and yet we have hitherto had no distinct Lexicon, in which their constituent parts and technical terms have been explained, with that amplitude and precision, which the great improvements of the Moderns, as well as the rising dignity of the Subject, seem to demand.

THE only works of this kind in the English language, deserving of notice, are Harris's Lexicon Technicum, and Stone's Mathematical Dictionary; the former of which, though a valuable performance at the time it was written, is now become too dry and obsolete to be referred to with pleasure or satisfaction: and the latter, consisting only of one volume in 8vo, must be regarded merely as an unfinished sketch, or brief compendium, extremely limited in its plan, and necessarily deficient in useful information.

IT became, therefore, the only resource of the Reader, in many cases where explanation was wanted, to have recourse to Chambers's Dictionary, in four large volumes folio, or to the Encyclopædia Britannica, now in eighteen large volumes 4to, or the still more stupendous performance of the French Encyclopedists; and even here his expectations might be frequently disappointed. These great and useful works, aiming at a general comprehension of the whole circle of the Sciences, are sometimes very deficient in their descriptions of particular branches; it being almost impossible, in such extensive undertakings, to appreciate, with exactness, the due value of every article. They are, besides, so voluminous and hetero-

geneous in their nature, as to render a frequent reference to them extremely inconvenient ; and even if this were not the case, their high price puts them out of the reach of the generality of readers.

WITH a view to obviate these defects, the Public are here presented with a Dictionary of a moderate size and price, which is devoted solely to Philosophical and Mathematical subjects. It is a work for which materials have been collecting through a course of many years ; and is the result of great labour and reading. Not only most of the Encyclopedias already extant, and the various publications of the Learned Societies throughout Europe, have been carefully consulted, but also all the original works, of any reputation, which have hitherto appeared on these subjects, from the earliest writers down to the present times.

FROM the latter of these sources, in particular, a considerable portion of information has been obtained, which the curious reader will find, in many cases, to be highly interesting and important. The History of Algebra, for instance, which is detailed at considerable length in the first volume, under the head of that article, will afford sufficient evidence to show in what a superficial and partial way the inquiry has been hitherto investigated, even by professed writers on the subject ; the principal of whom are M. Montucla, our countryman the celebrated Dr. Wallis, and the Abbé De Gua, a late French author, who has pretended to correct the Doctor's errors and misrepresentations.

REGULAR historical details are in like manner given of the origin and progress of each of these Sciences, as well as of the inventions and improvements by which they have been gradually brought from their first rude beginnings to their present advanced state.

It is also to be observed, that besides the articles common to the generality of Dictionaries of this kind, an interesting Biographical Account is here introduced of the most celebrated Philosophers and Mathematicians, both ancient and modern ; among which will be found the Lives of eminent characters, who have hitherto been either wholly overlooked, or very imperfectly recorded. Complete lists of their works are also subjoined to each article, when they could be procured ; which cannot but prove highly acceptable to that class of readers, who are desirous of obtaining the most satisfactory information on the subjects of their particular inquiries and pursuits. On the head of Biography, however, the Author has still to lament the want of many other respectable names which he was desirous to have

added to his list of authors, not having been able to procure any circumstantial accounts of their lives. He could have wished to have comprised in his list, the lives of all such public literary characters as the University Professors of Astronomy, Philosophy, and Mathematics, as well as those of the other more respectable class of authors on those sciences. He will therefore thankfully receive the communication of any such memoirs from the hands of gentlemen possessed of them; as well as hints and information on such useful improvements in the sciences as may have been overlooked in this Dictionary, or any articles that may here have been imperfectly or incorrectly treated; that he may at some future time, by adding them to this work, render it still more complete and deserving the public notice.

As this work is an attempt to separate the words in the sciences of Astronomy, Mathematics, and Philosophy, from those of other arts or sciences, in several of which there are already separate Dictionaries; as in Chemistry, Geography, Music, Marine and Naval affairs, &c; words sometimes occurred which it was rather doubtful whether they could be considered as properly belonging to the present work or not; in which case many of such words have been here inserted. But such as appeared clearly and peculiarly to belong to any of those other subjects, have been either wholly omitted, or else have had a very short account only given of them. The readers of this work therefore, recollecting that it is not a General Dictionary of all the Arts and Sciences, will not expect to find all sorts of words and subjects here treated of; but such only as peculiarly appertain to the proper matter of the work. And therefore, although some few words may inadvertently have been omitted; yet when the Reader does not immediately find every word which he wishes to consult, he will not always consider them as omissions of the Author, but for the most part as relating to some other science foreign to this Dictionary.

IN all cases where it could be conveniently done, the necessary figures and diagrams are inserted in the same page with the subjects which they are designed to elucidate; a method which will be found much more commodious than that of putting them in separate plates at the end of each volume, but, which has added very considerably to the expence of the undertaking. Where the subjects are of such a nature that they could not be otherwise well represented, they are engraved on copperplates.

As the whole of this work was written before it was put to the press, the Reader will find it of an equal and uniform nature and construction throughout; in which respect many

publications of this kind are very defective, from the subjects being diffusely treated under the first letters of the alphabet, while articles of equal importance in the latter part are so much abridged as to be rendered almost useless, in order that the whole might be comprised in a limited number of sheets, according to proposals made before the works were composed. The present Dictionary having been completed without any of these unfavourable circumstances, will be found in most cases equally instructive and useful, and may be consulted with no less advantage by the Man of Science than the Student.

IN addition to the foregoing original account of this work, we have to observe, that the whole has been several times carefully perused, in order to correct, enlarge, and amend the several articles; that all the new discoveries and improvements in the sciences, since the first composing of the work, have been attentively collected and abridged, for introducing in this new edition; that many new articles have been inserted in their places through the volumes, and even several of the chief articles of some of the other sciences &c, have now been included,—as Electricity, Galvanism, Voltaic pile, Acid, Alkali, Freezing, New Planets and Comets, with numerous other similar articles; that a large collection of new and interesting lives of eminent authors have been inserted, as far as materials could be obtained, and the merits of the authors were deemed worthy of notice in this work; that several new plates and figures have been added; that the pages have been considerably enlarged, and the printing so arranged and contrived as to include more matter in the sheets. In short, the alterations, additions, and other improvements, are so numerous, and so large, as entitle the present edition to be considered almost as an entire new work.

PHILOSOPHICAL AND MATHEMATICAL DICTIONARY.

A.

ABACIST, an Arithmetician. In this sense we find the word used by William of Malmesbury, in his History de Gestis Anglorum, written about the year 1150; where he shows that one Gerbert, a learned monk of France, who afterwards became pope of Rome in the year 998 or 999, by the name of Silvester the 2d, was the first who got from the Saracens the abacus, and that taught such rules concerning it, as the Abacists themselves could hardly understand.

ABACUS, in Arithmetic, an ancient instrument used by most nations for casting up accounts, or performing arithmetical calculations. It is by some derived from the Greek *αετός*, which signifies a cupboard or beaufet, perhaps from the similarity of the form of this instrument; and by others it is derived from the Phœnician *abak*, which signifies dust or powder, because it was said that this instrument was sometimes a square board or tablet, which was powdered over with fine sand or dust, in which were traced the figures or characters used in making calculations, which could thence be easily defaced, and the abacus refitted for use. But Lucas Paciolus, in the first part of his second distinction, thinks it is a corruption of Arabicus, by which he meant their Algorithm, or the method of numeral computation received from them.

We find this instrument in use for computation, under some variations, with most nations; as the Greeks, Romans, Germans, French, Chinese, &c.

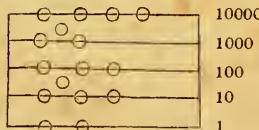

The Grecian Abacus was an oblong frame, over which were stretched several brass wires, strung with little ivory balls, like the beads of a necklace; by the various arrangements of which, all kinds of computations were easily made. Mahudel, in Hist. Acad. R. Inscr. tom. 3. p. 390.

The Roman Abacus was a little varied from the Grecian, having pins sliding in grooves, instead of strings or wires and beads. Philos. Trans. No. 180.

The Chinese Abacus, or Shwan-pun, like the Grecian, consists of several series of beads strung on brass wires, stretched from the top to the bottom of the instrument, and divided in the middle by a cross piece from side to side. In the upper space every string has two beads, which are each counted for 5; and in the lower space every string has five beads, of different values, the first being counted as 1, the second as 10, the third as 100, and so on, as with us. See SHWAN-PUN.

VOL. I.

The Abacus chiefly used in European countries, is nearly on the same principles, though the use of it is here more limited, because of the arbitrary and unequal divisions of money, weights, and measures, which, in China, are all divided in a tenfold proportion, like our scale of common numbers. This is made by drawing any number of parallel lines, like paper ruled for music, at such a distance as may be at least equal to twice the diameter of the calculus, or counter. Then the value of these lines, and of the spaces between them, increases, from the lowest to the highest, in a tenfold proportion. Thus, counters placed upon the first line, signify so many units or ones; on the second line 10's, on the third line 100's, on the fourth line 1000's, and so on. In like manner a counter placed in the first space, between the first and second line, denotes 5, in the second space 50, in the third space 500, in the fourth 5000, and so on. So that there are never more than four counters placed on any line, nor more than one placed in any space, this being of the same value as five counters on the next line below. Thus, the counters on 'the Abacus, in the following figure, express the number or sum 47382.

Besides the above instruments of computation, several others have been invented by different persons: as, Napier's Rods or Bones, described in his Rhabdologia, which see, under the word NAPIER; also the Abacus Rhabdologicus, a variation of Napier's, which is described in the first vol. of Machines et Inventions approuvées par l'Academie Royale des Sciences. An ingenious and general one was also invented by Mr. Gamaliel Smethurst, and is described in the Philosophical Transactions, vol. 46; where the inventor remarks that computations by it are much quicker and easier performed than by the pen, are also less burthensome to the memory, and can be performed by blind persons, or in the dark as well as in the light. A very comprehensive instrument of this kind was also contrived by the late learned Dr. Nicholas Saunderson, the blind professor of mathematics, by which he performed

B

very intricate calculations : an account of it is prefixed to the first volume of his Algebra, where it is called by the editor Palpable Arithmetic: which see.

In the Edinb. Rev. vol. 18, p. 205, is the following neat account of this instrument:—It is curious to observe, that the term *Calculation* itself claims no higher descent than from *calculus*, a pebble. A table strewed with fine sand, the *pulvis eruditus* of the poets, served both for tracing geometrical diagrams, and teaching the elements of writing; a very primitive contrivance, but universally used throughout the East, from which it has lately been imported into this country. The board on which arithmetical operations were performed, at first by means of pebbles, was named Abacus, from the Greek ἀβάξ; probably because originally it was only a writing-table of a compendious form, and designed for instructing children in their alphabet.

Nec qui *Abaco* numeros, et secto in pulvere metas
Scit risisse vafer. PERS. Sat. i. 138.

The Abacus was divided, from the right to the left hand, by vertical columns, on which the pebbles were placed, to denote, units, tens, hundreds, thousands, &c. The labour of counting and arranging those pebbles was afterwards sensibly abridged, by drawing across the board a horizontal line, above which, each single pebble had the power of 5. In the progress of luxury, *tali*, or dies made of ivory, were used instead of pebbles, and small silver coins came to supply the place of counters. But the operations with the abacus were rendered still more commodious, by substituting for such tali or counters, small beads strung on parallel threads, and sometimes pegs stuck along grooves.—Accountants by profession, among the Romans, were hence styled *calculatores*, or *ratiocinarii*. Various expedients seem to have been employed for shortening the arithmetical operations. The different positions of the fingers were, for that purpose, used to a certain extent. Boethius treated largely of the subject; and even the venerable Bede has given very diffuse rules for what was called *digital arithmetic*.

But the application of the abacus itself was not entirely forgotten at a much later period. Witness the small volume of arithmetic, quaintly composed in the form of dialogue by Robert Recorde, teacher of mathematics and practitioner in physic at Cambridge, during the reign of Edward VI.; in which round dots, placed on perpendicular lines, and employed to express the succession of units, tens, hundreds, &c., are made to perform some of the simpler numerical operations.—A small instrument, entirely resembling the abacus, has likewise at different times been recommended, for teaching the elements of ciphering, under the name of palpable arithmetic.

ABACUS, *Pythagorean*, so denominated from its inventor, Pythagoras, is a table of numbers, contrived for readily learning the principles of arithmetic; being probably what is now called the multiplication-table.

ABACUS, or *ABACISCUS*, in Architecture, the upper part or member of the capital of a column; serving as a crowning both to the capital and to the whole column. Vitruvius informs us that the *Abacus* was originally intended to represent a square flat tile laid over an urn, or a basket; and the invention is ascribed to Calimachus, an ingenious statuary of Athens, who, it is said, adopted it on observing a small basket, covered with a tile, over the root of an Acanthus plant, which grew on the grave of a

young lady; the plant shooting up, encompassed the basket, till meeting with the tile, it curled back in a kind of scroll: Calimachus passing by, took the hint, and immediately executed a capital on this plan; representing the tile by the Abacus, the leaves of the acanthus by the volutes, and the basket by the vase or body of the capital. See *ACANTHUS*.

ABACUS is also used by Scamozzi for a concave moulding in the capital of the Tuscan pedestal. And the word is used by Palladio for other members, which he describes. In ancient architecture, the same term is used to denote certain compartments in the incrustation or lining of the walls of state-rooms, mosaic-pavements, and the like. There were *Abaci* of marble, porphyry, jasper, alabaster, and even glass; variously shaped, as square, triangular, and such-like.

ABACUS Logisticus is a right-angled triangle, whose sides, about the right-angle, contain all the numbers from 1 to 60; and its area, the products of each two of the opposite numbers. This is also called a *canon of sexagesimals*, and is no other than a multiplication-table carried to 60 both ways.

ABACUS et *Palmula*, in the Ancient Music, denote the machinery by which the strings of the polypectra, or instruments of many strings, were struck, with a plectrum made of quills.

ABACUS Harmonicus is used by Kircher for the structure and disposition of the keys of a musical instrument, either to be touched with the hands or feet.

ABACUS, in Geometry, a table or slate upon which schemes or diagrams are drawn.

ABATIS, or *ABATTIS*, from the French *abattre*, to throw down, or beat down, in the Military Art, denotes a kind of retrenchment made by a quantity of whole trees cut down, and laid lengthways beside each other, the closer the better, having all their branches pointed towards the enemy, which prevents his approach, at the same time that the trunks serve as a breast-work before the men. The Abattis is a very useful work on most occasions, especially on sudden emergencies, when trees are near at hand; and has always been practised with considerable success, by the ablest commanders in all ages and nations.

ABAUZIT, *Firmin*, a learned and ingenious mathematician and philosopher, born at Uscz, in Languedoc, on the 11th of November 1679; his parents being protestants, he was obliged to leave France by the revocation of the edict of Nantes, and after suffering many hardships, at length found an asylum in Geneva, where he prosecuted his studies with the greatest success; and though his chief attention was directed to the mathematics, he nevertheless made considerable progress in every department of literature; he was acquainted with most of the learned men of his time, and among others with our illustrious countryman Sir Isaac Newton, who in an epistolary correspondence does him the honour to say, “you are a very fit person to judge between Leibnitz and me.” He seems induced to have perfectly understood the Principia, having undertaken the defence of it against father Castell, wherein he displayed great talents and ability: he discovered an error in that work when it first appeared, which was corrected in the next edition. After having signalized himself as much for his virtue as his learning, he died on the 20th of March 1767, at the advanced age of 87 years, lamented and regretted by all whom he honoured with his friendship.

ABBREVIATE; to abbreviate fractions, in Arithmetic and Algebra, is to lessen proportionally their terms, or the numerator and denominator; which is performed by dividing those terms by any number or quantity, which will divide them without leaving a remainder. And when the terms cannot be any further so divided, the fraction is said to be in its least terms.

$$\text{So } \frac{16}{24} = \frac{8}{12} = \frac{4}{6} = \frac{2}{3},$$

by dividing the terms continually by 2.

$$\text{And } \frac{294}{504} = \frac{147}{252} = \frac{49}{84} = \frac{7}{12},$$

by dividing by 2, 3, and 7.

$$\text{Also } \frac{3 \times 8 \times 5}{6} = \frac{8 \times 5}{2} = 4 \times 5 = 20.$$

by dividing by 3 and by 2.

$$\text{And } \frac{12ax^2}{4ax} = \frac{3x^2}{c}, \text{ by dividing by } 4ax.$$

$$\text{And } \frac{ab^2 + b^2x}{ax + x^2} = \frac{b^2}{x}, \text{ by dividing by } a + x.$$

ABBREVIATION, of fractions, in Arithmetic and Algebra, is the reducing them to lower terms, as in the examples above.

ABERRATION, in Astronomy, an apparent motion of the celestial bodies, occasioned by the progressive motion of light, and the earth's annual motion in its orbit.

This effect may be explained and familiarized by the motion of a line parallel to itself, much after the manner of the composition and resolution of forces. For this purpose, let the ratio of the velocity of light to that of the earth in its orbit, be as the line $b\ c$ to $a\ c$; then, by the composition of these two motions, the particle of light will seem to describe the line $b\ a$ or $d\ c$, instead of its real course $b\ c$; and will appear in the direction $a\ b$ or $c\ d$, instead of its true direction $c\ b$. So that, if $a\ b$ represent a tube, carried with a parallel motion by an observer along the line $a\ c$, in the time that a particle of light would move over the space $b\ c$, the different places of the tube being $a\ b$, $a\ b$, $c\ d$, $c\ d$; and when the eye, or end of the tube, is at a , let a particle of light enter the other end at b ; then, when the tube is at $a\ b$, the particle of light will be at e , exactly in the axis of the tube; and when the tube is at $c\ d$, the particle of light will arrive at f , still in the axis of the tube; and lastly, when the tube arrives at $c\ d$, the particle of light will arrive at the eye or point c , and consequently will appear to come in the direction $d\ c$ of the tube, instead of the true direction $b\ c$; and so on; one particle succeeding another, and forming a continued stream or ray of light in the apparent direction $d\ c$. So that the apparent angle made by the ray of light with the line $a\ e$, is the angle $d\ c\ e$, instead of the true angle $b\ c\ e$; and the difference, $b\ c\ d$ or $a\ b\ c$, is the quantity of the aberration.

M. de Maupertuis, in his Elements of Geography, gives also a familiar and ingenious idea of the aberration, in this manner: "It is thus," says he, "concerning the direction in which a gun must be pointed to strike a bird in its flight; instead of pointing it straight to the bird, the fowler will point a little before it, in the path of its

flight, and that so much the more as the flight of the bird is more rapid, with respect to the flight of the shot." In this way of considering the matter, the flight of the bird represents the motion of the earth, or the line $a\ c$, in our scheme above, and the flight of the shot represents the motion of the ray of light, or the line $b\ c$.

M. Clairaut too, in the Memoirs of the Academy of Sciences for the year 1746, illustrates this effect in a familiar way, by supposing drops of rain to fall rapidly and quickly after each other from a cloud, under which a person moves with a very narrow tube; in which case it is evident that the tube must have a certain inclination, in order that a drop which enters at the top, may fall freely through the axis of the tube, without touching its sides; which inclination must be more or less according to the velocity of the drops, in respect to that of the tube: then the angle made by the direction of the tube and of the falling drops, is the aberration arising from the combination of those two motions.

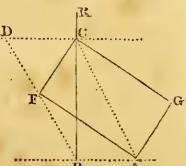

Another ingenious and familiar illustration of this effect is given in the *Encyclopédie Méthodique*; which is nearly as follows.

Let $c\ f\ a\ g$ represent a boat, or other vessel, moving parallel to itself from c to d , and suppose a person at c to throw a stone towards a , with such a velocity that it exactly arrives there when the point a arrives at b , by the motion of the boat; now a person situated at a will naturally refer the direction of the stone to the diagonal $c\ a$ or $d\ b$ of the boat, over which it has actually passed, notwithstanding its real direction is that of $c\ b$; for the same appearances would have taken place, had the stone been cast from c to b , provided its velocity had been such as to cause it to arrive at b , in the same time as before.

This therefore explains the nature of the aberration of the celestial bodies; for if we now consider the stone above mentioned as a particle of light issuing from a body at c , in the direction $c\ b$, and that it arrives there in the same time that a person moves from a to b ; then it is evident, from what is said above, that he will refer its direction to the line $d\ b$; but all bodies appear in the direction of the visual rays emitted by them, and consequently the point d will be the apparent place of the body c . And thus the effect of aberration is always to make bodies appear more advanced in the direction we are moving, than they really are.

This discovery, which is one of the brightest that have been made in the last age, we owe to the accuracy and ingenuity of the late Dr. Bradley, afterwards Astronomer Royal; to which he was occasionally led by the result of some accurate observations which he had made with another view, namely, to determine the annual parallax of the fixed stars, or that which arises from the motion of the earth in its annual orbit about the sun.

This motion of the earth, about the sun, had been often doubted, and warmly contested. The defenders of that doctrine, among other proofs of its reality, conceived the idea of adducing an incontestable one from the annual parallax of the fixed stars, if they should be within such a distance, or if instruments and observations could be made with such accuracy, as to render that

parallax sensible; and with this view various attempts have been made. Before the observations of M. Picard, made in 1672, it was the general opinion, that the stars did not change their position during the course of a year. Tycho Brahe and Riccioli fancied that they had assured themselves of it from their observations; from which they concluded that the earth did not move round the sun, and that there was no annual parallax in the fixed stars. M. Picard, in the account of his Voyage d'Uranibourg, made in 1672, says that the pole star, at different times of the year, has certain variations which he had observed for about 10 years, and which amounted to near $40''$ a year: whence some, who favoured the annual motion of the earth, were led to conclude that these variations were the effect of the parallax of the earth's orbit. But it was impossible to explain it by that parallax; because this motion was in a manner contrary to what ought to follow only from the motion of the earth in its orbit.

In 1674 Dr. Hook published an account of observations, made by him in 1669, by which he had found that the star γ Draconis was $23''$ more northerly in July than in October: observations which, at that time, seemed to favour the opinion of the earth's motion, though it be now known that there could not be any accuracy in them.

Flamsteed having observed the pole star with his mural quadrant, in 1689 and the following years, found that its declination was $40''$ less in July than in December; which observations, though very just, were yet, however, improper for proving the annual parallax: and he recommended the making of an instrument of 15 or 20 feet radius, to be firmly fixed on a strong foundation, for deciding a doubt which was otherwise not soon likely to be brought to a conclusion.

In this state of uncertainty and doubt, Dr. Bradley, in conjunction with Mr. Samuel Molineux, in the year 1725, formed the project of verifying, by a series of new observations, those which Dr. Hook had communicated to the public almost 50 years before. And as it was his attempt that chiefly gave rise to this undertaking, so it was his method in making the observations, in some measure, that they followed; for they made choice of the same star, and their instrument was constructed on nearly the same principles: but had it not greatly exceeded the former in exactness, they might still have continued in uncertainty and doubt, as to the parallax of the fixed stars. And this was chiefly owing to the accuracy of the ingenious Mr. George Graham, to whom the lovers of astronomy are also indebted for several other exact and convenient instruments.

The success then of the intended experiment, evidently depending very much on the accuracy of the instrument, that leading object was first to be well secured. Mr. Molineux's apparatus having been completed, and fitted for observing, about the end of November 1725, on the third day of December following, the bright star in the head of Draco, marked γ by Bayer, was for the first time observed, as it passed near the zenith, and its situation carefully taken with the instrument. The like observations were made frequently, on many days, both in that and the succeeding months, when they found a gradual variation in the star's position towards the south. They took care to examine very nicely, at the time of each observation, how much the variation was; till about the beginning of March 1726, when the star was found to be

$20''$ more southerly than at the time of the first observation: it now indeed seemed to have arrived at its utmost limit southward, as in several trials, made about this time, no sensible difference was observed in its situation. By the middle of April, it appeared to be returning back again towards the north; and about the beginning of June, it passed at the same distance from the zenith, as it had done in December, when it was first observed.

From the quick alteration in the declination of the star about this time, increasing about one second in 3 days, it was conjectured that it would now proceed northward of its present situation, as it had before gone southward; which happened accordingly; for the star continued to move northward till September following, when it became stationary again; being then near $20''$ more northerly than in June, and upwards of $39''$ more northerly than it had been in March. From September the star again returned towards the south, till, in December, it arrived at the same situation in which it had been observed twelve months before, allowing for the difference of declination on account of the precession of the equinox.

This was a sufficient proof that the instrument had not been the cause of this apparent motion of the star; and yet it seemed difficult to devise one that should be adequate to such an unusual effect. A nutation of the earth's axis was one of the first things that offered itself on this occasion; but it was soon found to be insufficient.

The great regularity of the observations left no room to doubt, but that there was some uniform cause by which this unexpected motion was produced, and which did not depend on the uncertainty or variety of the seasons of the year. But not being able to frame any hypothesis, sufficient to account for all the phenomena, and being very desirous to search a little further into this matter, Dr. Bradley began to think of erecting an instrument for himself at Wanstead; that, having it always at hand, he might with the more ease and certainty inquire into the laws of this new motion. The consideration likewise of being able, by another instrument, to confirm the truth of the observations hitherto made with that of Mr. Molineux's, was no small inducement to the undertaking; but the principal one was, the opportunity he should thereby have of trying in what manner other stars should be affected by the same cause, whatever it might be. For Mr. Molineux's instrument being originally designed for observing γ Draconis, to try whether it had any sensible parallax, it was so contrived, as to be capable of but little alteration in its direction; not above 7 or 8 minutes of a degree: and there being but few stars, within half that distance from the zenith of Kew, bright enough to be well observed, he could not, with his instrument, thoroughly examine how this cause affected stars that were differently situated, with respect to the equinoctial and solstitial points of the ecliptic.

These considerations determined him; and by the contrivance and direction of the same ingenious person, Mr. Graham, his instrument was fixed upon the 19th of August 1727. As he had no convenient place where he could make use of so long a telescope as Mr. Molineux's, he contented himself with one of but little more than half the length, namely, of 12 feet and a half, the other being 24 feet and a half long, judging, from the experience he had already had, that this radius would be long enough to

adjust the instrument to a sufficient degree of exactness : and he had no reason afterwards to change his opinion ; for by all his trials he was very well satisfied, that when it was carefully rectified, its situation might be securely depended on to half a second.

His instrument being fixed, he immediately began to observe such stars as he judged most proper to give him any light into the cause of the motion already mentioned. There was a sufficient variety of small ones, and not less than twelve that he could observe through all seasons of the year, as they were bright enough to be seen in the day-time, when nearest the sun.

When the year was completed, he began to examine and compare his observations ; and having pretty well satisfied himself as to the general laws of the phenomena, he then endeavoured to find out the cause of them. He was already convinced that the apparent motion of the stars was not owing to a nutation of the earth's axis. The next idea that occurred to him, was an alteration in the direction of the plumb-line, by which the instrument was constantly adjusted ; but this, upon trial, proved insufficient. He then considered what refraction might do ; but here also he met with no satisfaction. At length, through an amazing sagacity, he conjectured that all the phenomena hitherto mentioned, proceeded from the progressive motion of light, and the earth's annual motion in its orbit : for he conceived, that if light were propagated in time, the apparent place of a fixed object would not be the same when the eye is at rest, as when it is moving in any other direction except that of the line passing through the object and the eye ; and that when the eye is moving in different directions, the apparent place of the object would be different.

He considered this matter in the following manner. He imagined $c\alpha$ to be a ray of light, falling perpendicularly on the line $b\beta$: then, if the eye be at rest at α , the object must appear in the direction αc , whether light be propagated in time, or instantaneously. But if the eye be moving from b towards a , and light be propagated in time, with a velocity that is to the velocity of the eye, as αc to αb ; then, light moving from c to a , while the eye moves from b to a , that particle of it by which the object will be discerned, when the eye in its motion comes to a , is at c when the eye is at b . Joining the points b, c , he supposed the line bc to be a tube, inclined to the line $b\beta$ in the angle $c\beta b$, and of such a diameter as to admit of but one particle of light : then it was easy to conceive, that the particle of light at c , by which the object must be seen when the eye arrives at a , would pass through the tube bc , so inclined to the line $b\beta$, and accompanying the eye in its motion from b to a ; and that it would not come to the eye, placed behind such a tube, if it had any other inclination to the line $b\beta$. But if, instead of supposing bc so small a tube, we conceive it to be the axis of a larger ; then, for the same reason, the particle of light at c cannot pass through that axis, unless it be inclined to $b\beta$ in the same angle $c\beta b$.

In like manner, if the eye move the contrary way, from b towards a , with the same velocity ; then the tube must be inclined in the angle $\beta c b$. Although therefore the true or real place of an object, be perpendicular to

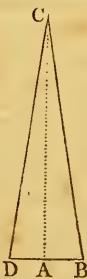

the line in which the eye is moving, yet the visible place will not be so ; since that must doubtless be in the direction of the tube. But the difference between the true and apparent place, will be, *ceteris paribus*, greater or less, according to the different proportions between the velocity of light and that of the eye : so that, if we could suppose light to be propagated in an instant, then there would be no difference between the real and visible place of an object, though the eye were in motion ; for in that case, αc being infinite with respect to αb , the angle $\alpha c b$, which is the difference between the true and visible place, vanishes. But if light be propagated in time, which was then allowed by most philosophers, then it is evident, from the foregoing considerations, that there will always be a difference between the true and visible place of an object, except when the eye is moving either directly towards, or from the object. And in all cases, the sine of the difference between the true and visible place of the object, will be to the sine of the visible inclination of the object to the line in which the eye is moving, as the velocity of the eye, is to the velocity of light.

If light moved only 1000 times faster than the eye, and an object, supposed to be at an infinite distance, were really placed perpendicularly over the plane in which the eye is moving ; it follows, from what has been said, that the apparent place of such object will always be inclined to that plane, in an angle of $89^{\circ} 56' \frac{1}{2}$; so that it will constantly appear $3' \frac{1}{2}$ from its true place, and will seem so much less inclined to the plane, that way towards which the eye tends. That is, if αc be to αb or αd , as 1000 to 1, the angle $\alpha b c$ will be $89^{\circ} 56' \frac{1}{2}$, and the angle $\alpha c b 3' \frac{1}{2}$, and $\beta c d$ or $2\alpha c b$ will be $7'$, if the direction of the motion of the eye be contrary at one time to what it is at another.

If the earth revolve about the sun annually, and the velocity of light were to the velocity of the earth's motion in its orbit, as 1000 is to 1 ; then it is easy to conceive, that a star really placed in the pole of the ecliptic, would to an eye carried along with the earth, seem to change its place continually ; and, neglecting the small difference on account of the earth's diurnal revolution on its axis, it would seem to describe a circle about that pole, every where distant from it by $3' \frac{1}{2}$. So that its longitude would be varied through all the points of the ecliptic every year, but its latitude would always remain the same. Its right ascension would also change, and its declination, according to the different situations of the sun in respect of the equinoctial points ; and its apparent distance from the north pole of the equator, would be 7° less at the autumnal, than at the vernal equinox.

The greatest alteration of the place of a star, in the pole of the ecliptic, or, which in effect amounts to the same thing, the proportion between the velocity of light and the earth's motion in its orbit, being known, it will not be difficult to find what would be the difference, on this account, between the true and apparent place of any other star at any time : and, on the contrary, the difference between the true and apparent place being given, the proportion between the velocity of light, and the earth's motion in its orbit, may be found.

After the history of this curious discovery, related by the author (in the Philos. Trans. of that year), he gives the results of a multitude of accurate observations, made on a great number of stars, at all seasons of the year. From all which observations, and the foregoing theory, he

found that every star, in consequence of the earth's motion in its orbit and the progressive motion of light, appears to describe a small ellipse in the heavens, the transverse axis of which is equal to the same quantity for every star, namely $40''$ nearly; and that the conjugate axis of the ellipse, for different stars, varies as the sine of the star's latitude; that is, radius is to the sine of the star's latitude, as the transverse axis to the conjugate axis: and consequently a star in the pole of the ecliptic, its latitude being there 90° , whose sine is equal to the radius, will appear to describe a small circle about that pole as a centre, whose radius is equal to $20''$. He also gives the following law of the variation of the star's declination: if α denote the angle of position, or the angle at the star made by two great circles drawn from it through the poles of the ecliptic and equator, and β another angle, whose tangent is to the tangent of α , as radius is to the sine of the star's latitude; then β will be equal to the difference of longitude between the sun and the star, when the true and apparent declination of the star are the same. And if the sun's longitude in the ecliptic be reckoned from that point in which it is when this happens; then the difference between the true and apparent declination of the star, will be always as the sine of the sun's longitude from that point. It will also be found that the greatest difference of declination that can be between the true and apparent place of the star, will be to $20''$, the semitransverse axis of the ellipse, as the sine of α to the sine of β .

The author then shows, by the comparison of a number of observations made on different stars, that they exactly agree with the theory deduced from the progressive motion of light, and that consequently it is highly probable that such motion is the cause of those variations in the situation of the stars. From which he infers, that the parallax of the fixed stars is much smaller than hitherto supposed, by those who pretended to deduce it from observations. He thinks he may venture to say that, in the stars he had observed, the parallax does not amount to $2''$; nay, that if it had amounted to $1'$, he should certainly have perceived it, in the great number of observations that he made, especially of γ Draconis: which agreeing with the hypothesis, without allowing anything for parallax, nearly as well when the sun was in conjunction with, as in opposition to, this star, it seems very probable that its parallax is not so much as one second; and consequently that it is above 400000 times farther from us than the sun.

From the greatest variation in the place of the stars, namely $40''$, Dr. Bradley deduces the ratio of the velocity of light, in comparison with that of the earth in its orbit. In the preceding figure, αc is to αb , as the velocity of light to that of the earth in its orbit, the angle $c\alpha b$ being equal to $20''$; so that the ratio of those velocities is that of radius to the tangent of $20''$, or of radius to the arc of $20''$, since in very small angles the tangent has no sensible difference from the arc itself: but the radius of a circle is equal to the arc of $57^{\circ}\frac{1}{18}$ nearly, or equal to $206260''$; therefore the velocity of light is to the velocity of the earth, as 206260 to 20 , or as 10313 to 1 .

And hence also the time, in which light passes over the space from the sun to the earth, is easily deduced; for this time will be to one year, as αb or $20''$ to $3600''$ of the whole circle; that is, $3600 : 20' :: 365\frac{1}{4} \text{ days} : 8m 7s$; that is, light will pass from the sun to the earth in 8 minutes, 7 seconds; and this will be the same, whatever may be

the distance of the sun. See Abridg. Philos. Trans. vol. 7, p. 308, and vol. 9, p. 417.

Dr. Bradley having annexed to his theory the rules or formulae for computing the aberration of the fixed stars in declination and right ascension; these rules have been variously demonstrated, and reduced to other practical forms, by Clairaut, in the Memoirs of the Academy of Sciences for 1737; by Simpson, in his Essays in 1740; by Fontaine, in 1744; and by several other persons. The results of these rules are as follow: Every star appears to describe in the course of a year, by means of the aberration, a small ellipse, whose greater axis is $40''$, and the less axis, perpendicular to the ecliptic, is equal to $40''$ multiplied by the sine of the star's latitude, the radius being 1. The eastern extremity of the longer axis, marks the apparent place of the star, on the day of the opposition; and the extremity of the less axe, which is farthest from the ecliptic, marks its situation three months after.

The greatest aberration in longitude, is equal to $20''$ divided by the cosine of its latitude, or multiplied by its secant. And the aberration for any time, is equal to $20''$ multiplied by the cosine of the elongation of the star found for the same time, and divided by the cosine of its latitude, or multiplied by its secant. This aberration is subtractive in the first and last quadrants of the argument, or of the difference between the longitudes of the sun and star; and additive in the second and third quadrants. The greatest aberration in latitude, is equal to $20''$ multiplied by the sine of the star's latitude. And the aberration in latitude for any time, is equal to $20''$ multiplied by the sine of the star's latitude, and also by the sine of the elongation. The aberration is subtractive before the opposition, and additive after it.

The greatest aberration in declination, is equal to $20''$ multiplied by the sine of the angle of position α , and divided by the sine of β the difference of longitude between the sun and star when the aberration in declination is nothing. And the aberration in declination at any other time, will be equal to the greatest aberration multiplied by the sine of the difference between the sun's place at the given time and his place when the aberration is nothing. Also the sine of the latitude of the star, is to radius, as the tangent of α the angle of position at the star, is to the tangent of β , the difference of longitude between the sun and star when the aberration in declination is nothing. The greatest aberration in right-ascension, is equal to $20''$ multiplied by the cosine of α the angle of position, and divided by the sine of c the difference in longitude, between the sun and star when the aberration in right-ascension is nothing. And the aberration in right-ascension at any other time, is equal to the greatest aberration multiplied by the sine of the difference between the sun's place at the given time, and his place when the aberration is nothing. Also the sine of the latitude of the star is to radius, as the cotangent of α the angle of position, to the tangent of c .

In the first article of Mr. Simpson's Essays (an. 1740), is given a geometrical demonstration of a star's apparent path, resulting from the motion of light combined with the earth's motion in its annual orbit; accompanied with rules thence deduced for practical calculations. Another curious demonstration of the same was given by Dr. Brook Taylor in the year 1729, as soon as Dr. Bradley's discovery was known. It is preserved in Robins's Tracts, vol. 2, p. 276, and is as follows.—Let $a b c$ be the orbit of

the earth, in which it moves from b to c and a , round the sun in d . Then, the earth being in c , if the tangent $c e$ be drawn, and on the transverse axis $a b$ as a diameter the circle $a e b f$ be described, $d d$ being drawn and continued to e , $d e$ is perpendicular to the tangent $c e$; and therefore the velocity of the earth in b , is to the velocity in c , reciprocally as $d b$ to $d e$; that is, directly as $a b$ to $d g$, since the rectangles under $a b$ and $d g$ are equal. Now $c i$ being drawn from the earth in c , toward the true place of any star, take $c i$ to $a d$ as the velocity of light to the velocity of the earth in b . Through i draw $k l$ in a situation perpendicular to $a b$, and making $k i$ equal to $a d$, and $l i$ equal to $d b$, on the diameter $k l$ describe the circle $k m l n$ parallel to the plane $a c b f$. Lastly, make the angle under $k i o$ equal to that under $a d g$, which is nearly the arithmetical mean between the mean and true distance of the earth from the aphelion, and draw $c o$.—Now $k l$ being in a situation perpendicular to $a b$, and the angles under $k i o$, $a d g$ equal, $o i$ will be equal to $d g$, and be situated perpendicular to $g e$, and therefore is parallel to $c e$, or to the direction of the earth's motion in c ; and is to $k i$, as the velocity of the earth in c , to its velocity in b . Consequently, since $k i$ or $a d$ is to $c i$ as the velocity of the earth in b is to the velocity of light, by equality $o i$ is to $c i$, as the velocity of the earth's motion in c to the velocity of light. Therefore the star will be seen from the earth at c in the direction $c o$. Hence it follows, that every fixed star is viewed from the earth as moving in a circle parallel to the plane of the ecliptic, the diameter of that circle which is parallel to the lesser axis of the earth's orbit being divided by the true place of the star, in the same proportion, as the greater axis of the earth's orbit is divided by the sun.

ABERRATION of the Planets, is equal to their geocentric motion, or the space they appear to move through as seen from the earth, during the time that light employs in passing from the planet to the earth. Thus, in the sun, the aberration in longitude is constantly $20''$, that being the space moved by the sun, or, which is the same thing, by the earth, in $8^m 7^s$, that being the time in which light passes from the sun to the earth, as we have seen in the foregoing article. In like manner, knowing the distance of any planet from the earth, by proportion it will be, as the distance of the sun is to the distance of the planet, so is $8^m 7^s$ to the time of light passing from the planet to the earth: then computing the planet's geocentric motion in this time, that will be the aberration of the planet, whether it be in longitude, latitude, right-ascension, or declination.

It is evident that the aberration will be greatest in the longitude, and very small in latitude, because the planets deviate very little from the plane of the ecliptic or path of the earth; so that the aberration in the latitudes of the planets, is commonly neglected, as insensible; the greatest in Mercury being only $4\frac{1}{2}''$, and much less in the other planets. As to the aberrations in declination and right-ascension, they must depend on the situation of the planet in the zodiac. The aberration in longitude, being equal to the geocentric motion, will be more or less according as that motion is; it will therefore be least, or nothing at all,

when the planet is stationary; and greatest in the superior planets, Mars, Jupiter, Saturn, &c, when they are in opposition to the sun; but in the inferior planets, Venus and Mercury, the aberration is greatest at the time of their superior conjunction. These maxima of aberration for the several planets, Mercury $59''$ when their distance from the sun is least, are as annexed, viz, for

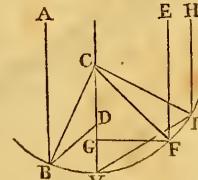

And between these numbers and nothing, the aberrations of the planets, in longitude, vary according to their situations. But that of the sun varies not, being constantly $20''$, as has been before observed. And this may alter his declination by a quantity, which varies from 0 to near $8''$; being greatest or $8''$ about the equinoxes, and vanishing in the solstices.

The methods of computing these, and the formulas for all cases, are given by M. Clairaut, in the Memoirs of the Academy of Sciences for the year 1746, and by M. Euler in the Berlin Memoirs, vol. 2, for 1746.

ABERRATION, in Optics, is the deviation or dispersion of the rays of light, when reflected by a speculum, or refracted by a lens, by which they are prevented from meeting or uniting in the same point, called the geometrical focus, but are spread over a small space, and produce a confusion of images. This aberration is either lateral or longitudinal: the lateral aberration is measured by a perpendicular to the axis of the speculum or lens, drawn from the focus to meet the refracted or reflected ray: the longitudinal aberration is the distance, on the axis, between the focus and the point where the ray meets the axis. The aberrations are very amply treated in Smith's Complete System of Optics, in 2 volumes 4to.

There are two species of aberration, distinguished according to their different causes: the one arises from the figure of the speculum or lens, producing a geometrical dispersion of the rays, when these are perfectly equal in all respects: the other arises from the unequal refrangibility of the rays of light themselves; a discovery that was made by Sir Isaac Newton, and for this reason it is often called the Newtonian aberration. As to the former species of aberration, or that arising from the figure, it is well known that if rays issue from a point at a given distance, then they will be reflected into the other focus of an ellipse having the given luminous point for one focus, or directly from the other focus of an hyperbola; and will be variously dispersed by all other figures. But if the luminous point be infinitely distant, or, which is the same, the incident rays be parallel, then they will be reflected by a parabola into its focus, and variously dispersed by all other figures. But those figures are very difficult to make, and therefore curved specula are commonly made spherical, the figure of which is generated by the revolution of a circular arc, which produces an aberration of all rays, whether they are parallel or not, and therefore it has no accurate geometrical focus which is common to all the rays.

Let $a b v$ represent a concave spherical speculum, whose centre is c ; and let $a b$, $e f$ be incident rays parallel to the axis $c v$. Because the angle of incidence

is equal to the angle of reflection in all cases, therefore if the radii $c b$, c be drawn to the points of incidence, and thence $b d$ making the angle $c b d$ equal to the angle $c b a$, and $f g$ making the angle $c f g$ equal to the angle $c f e$; then $b d$, $f g$ will be the reflected rays, and d , e , the points where they meet the axis. Hence it appears that the point of coincidence with the axis, is equally distant from the point of incidence and the centre: for because the angle $c b d$ is equal to the angle $c b a$, which is equal to the alternate angle $b c d$, therefore their opposite sides $c d$, $d b$ are equal: and in like manner, in any other, $f g$ is equal to $g c$. And hence it is evident that when b is indefinitely near the vertex v , then d is in the middle of the radius $c v$; and the nearer the incident ray is to the axis $c v$, the nearer will the reflected ray come to the middle point d ; and the contrary. So that the aberration $d c$ of any ray $e f g$, is always more and more, as the incident ray is farther from the axis, or the incident point r from the vertex v ; till when the distance $v r$ is 60 degrees, then the reflected ray falls in the vertex v , making the aberration equal to the whole length $d v$. And this shows the reason why specula are made of a very small segment of a sphere, namely, that all their reflected rays may arrive very near the middle point or focus d , to produce an image the most distinct, by the least aberration of the rays. And in like manner for rays refracted through lenses.

In spherical lenses, M. Huygens has demonstrated that the aberration from the figure, in different lenses, is as follows.

1. In all plano-convex lenses, having their plane surface exposed to parallel rays, the longitudinal aberration of the extreme ray, or that remotest from the axis, is equal to $\frac{2}{3}$ of the thickness of the lens.

2. In all plano-convex lenses, having their convex surface exposed to parallel rays, the longitudinal aberration of the extreme ray, is equal to $\frac{2}{7}$ of the thickness of the lens. So that in this position of the same plano-convex lens, the aberration is but about one-fourth of that in the former; being to it only as 7 to 27.

3. In all double convex lenses of equal spheres, the aberration of the extreme ray is equal to $\frac{2}{3}$ of the thickness of the lens.

4. In a double convex lens, the radii of whose spheres are as 1 to 6, if the more convex surface be exposed to parallel rays, the aberration from the figure is less than in any other spherical lens; being no more than $\frac{1}{44}$ of its thickness.

But the foregoing species of aberration, arising from the figure, is very small, and easily remedied, in comparison with the other, arising from the unequal refrangibility of the rays of light; insomuch that Sir Isaac Newton shows in his Optics, p. 84 of the 8vo edition, that if the object-glass of a telescope be plano-convex, the plane side being turned towards the object, and the diameter of the sphere, to which the convex side is ground, be 100 feet, the diameter of the aperture being 4 inches, and the ratio of the sine of incidence out of glass into air, be to that of refraction, as 20 to 31; then the diameter of the circle of aberrations will in this case be only $\frac{2}{7200000}$ parts of an inch: while the diameter of the little circle, through which the same rays are scattered, by unequal refrangibility, will be about the 55th part of the aperture of the object-glass, which here is 4 inches. And therefore the error arising from the spherical figure of the

glass, is to the error arising from the different refrangibility of the rays, as $\frac{2}{7200000}$ to $\frac{1}{55}$, that is as 1 to 5449.

So that it may seem strange that objects appear through telescopes so distinct as they do, considering that the error arising from the different refrangibility, is almost incomparably larger than that of the figure. Newton however solves the difficulty by observing that the rays, under their various aberrations, are not scattered uniformly over all the circular space, but collected infinitely more dense in the centre than in any other part of the circle; and that, in the way from the centre to the circumference, they grow more and more rare, so as at the circumference to become infinitely rare; and, by reason of their rarity, they are not strong enough to be visible, unless in the centre, and very near it.

In consequence of the discovery of the unequal refrangibility of light, and the apprehension that equal refractions must produce equal divergencies, in every kind of medium, it was supposed that all spherical object-glasses of telescopes would be equally affected by the different refrangibility of light, in proportion to their aperture, of whatever materials they might be constructed: and therefore, that the only improvement that could be made in refracting telescopes, was that of increasing their length. So that Sir Isaac Newton, and other persons after him, despairing of success in the use and fabric of lenses, directed their chief attention to the construction of reflecting telescopes.

However, about the year 1747, M. Euler applied himself to the subject of refraction; and pursued a hint suggested by Newton, for the design of making object-glasses with two lenses of glass inclosing water between them; hoping that, by constructing them of different materials, the refractions would balance one another, and so the usual aberration be prevented. Mr. John Dollond, an ingenious optician in London, minutely examined this scheme, and found that M. Euler's principles were not satisfactory. M. Clairaut likewise, whose attention had been excited to the same subject, concurred in opinion that Euler's speculations were more ingenious than useful. This controversy, which seemed to be of great importance in the science of optics, engaged also the attention of M. Klingenstierna of Sweden, who was led to make a careful examination of the 8th experiment in the second part of Newton's Optics, with the conclusions there drawn from it. The consequence was, that he found that the rays of light, in the circumstances there mentioned, did not lose their colour, as Sir Isaac had imagined. This hint of the Swedish philosopher led Mr. Dollond to re-examine the same experiment: and after several trials it appeared, that different substances caused the light to diverge very differently, in proportion to their general refractive powers. In the year 1757 therefore he procured wedges of different kinds of glass, and applied them together so, that the refractions might be made in contrary directions, that he might discover whether the refraction and divergency of colour would vanish together. The result of his first trials encouraged him to persevere; for he discovered a difference far beyond his hopes in the qualities of different kinds of glass, with respect to their divergency of colours. The Venice glass and English crown glass were found to be nearly allied in this respect: the common English plate glass made the rays diverge more; and the English flint glass most of all. But, without inquiring into the cause of this difference, he pro-

ceeded to adapt wedges of crown glass, and of white flint glass, ground to different angles, to each other, so as to refract in different directions; till the refracted light was entirely free from colours. Having measured the refractions of each wedge, he found that the refraction of the white glass, was to that of the crown glass, nearly as 2 to 3: and he hence concluded in general, that any two wedges made in this proportion, and applied together so as to refract in contrary directions, would refract the light without any aberration of the rays.

Mr. Dollond's next object was to make similar trials with spherical glasses of different materials, with the view of applying his discovery to the improvement of telescopes: and here he perceived that, to obtain a refraction of light in contrary directions, the one glass must be concave, and the other convex; and the latter, which was to refract the most, that the rays might converge to a real focus, he made of crown glass, the other of white flint glass. And as the refractions of spherical glasses are inversely as their focal distances, it was necessary that the focal distances of the two glasses, should be inversely as the ratios of the refractions of the wedges; because that, being thus proportioned, every ray of light that passes through this compound glass, at any distance from its axis, will constantly be refracted, by the difference between two contrary refractions, in the proportion required; and therefore the different refrangibility of the light will be entirely removed.

But in the applications of this ingenious discovery to practice, Mr. Dollond met with many and great difficulties. At length however, after many repeated trials, by a resolute perseverance, he succeeded so far as to construct refracting telescopes much superior to any that had hitherto been made; representing objects with great distinctness, and in their true colours.

M. Clairaut, who had interested himself from the beginning in this discovery, now endeavoured to ascertain the principles of Mr. Dollond's theory, and to lay down rules to facilitate the construction of these new telescopes. With this view he made several experiments, to determine the refractive power of different kinds of glass, and the proportions in which they separated the rays of light: and from these experiments he deduced several theorems of general use. M. d'Alembert made likewise a great variety of calculations to the same purpose; and he showed how to correct the errors to which these telescopes are subject, sometimes by placing the object-glasses at a small distance from each other, and sometimes by using eye-glasses of different refractive powers. But though foreigners were hereby supplied with the most accurate calculations, they were very defective in practice; and the English telescopes, made, as they imagined, without any precise rule, were greatly superior to the best of their construction.

M. Euler, whose speculations had first given occasion to this important and useful inquiry, was very reluctant in admitting Mr. Dollond's improvements, because they militated against a pre-conceived theory of his own. At last however, after several alterations, being convinced of their reality and importance by M. Clairaut, he assented; and he soon after received further satisfaction from the experiments of M. Zeiher, of Petersburg.

M. Zeiher showed by experiments, that it is the lead, in the composition of glass, which gives it this remarkable

property, namely, that while the refraction of the mean rays is nearly the same, that of the extreme rays considerably differs. And, by increasing the lead, he produced a kind of glass, which occasioned a much greater separation of the extreme rays than that of the flint glass used by Mr. Dollond, and at the same time considerably increased the mean refraction. M. Zeiher, in the course of his experiments, made glass of minium and lead, with a mixture also of alkaline salts; and he found that this mixture greatly diminished the mean refraction, while it made hardly any change in the dispersion: and he at length obtained a kind of glass greatly superior to the flint glass of Mr. Dollond, for the construction of telescopes; as it occasioned three times as great a dispersion of the rays as the common glass, while the mean refraction was only as 1:61 to 1.

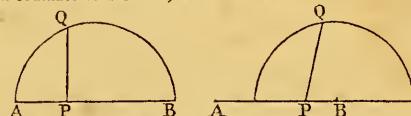

Other improvements were also made on the new or achromatic telescopes by the inventor Mr. John Dollond, and by his son Peter Dollond; which may be seen under the proper words. For various dissertations also on the subject of the aberration of light, colours, and the figure of the glass, see Philos. Trans. vols. 35, 48, 50, 51, 52, 55, 60; Memoirs of the Academy of Sciences of Paris, for the years 1737, 1746, 1752, 1755, 1756, 1757, 1762, 1764, 1765, 1767, 1770; the Berlin Acad. 1746, 1762, 1766; Swed. Mem. vol. 16; Com. Nov. Petropoli. 1762; M. Euler's Dioptrics; M. d'Alembert's Opuscules Math.; M. de Rochon Opuscules; &c., &c.

ABRIDGING, in Algebra, is the reducing a compound equation, or quantity, to a more simple form of expression. This is done either to save room, or the trouble of writing a number of symbols; or to simplify the expression, and ease the memory, or to render the formula more easy and general:

So the equation $x^3 - ax^2 + abx - abc = 0$, by putting $p = a$, $q = ab$, and $r = abc$, becomes $x^3 - px^2 + qx - r = 0$.

And the equation $x^2 + (a+b)x - \frac{ab}{c} = 0$, by putting $p = a+b$, and $q = \frac{ab}{c}$, becomes $x^2 + px - q = 0$.

ABSCISS, ABSCISSÉ, or ABSCISSA, is a part or segment cut off a line, terminated at some certain point, by an ordinate to a curve; as AP or BP.

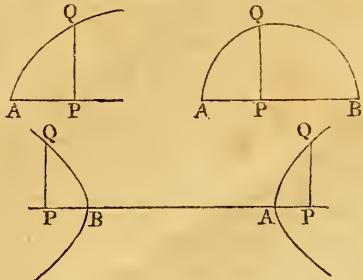

So that the absciss may either commence at the vertex of the curve, or at any other fixed point. And it may be taken either upon the axis or diameter of the curve, or upon any other line given in position.

Hence there are an infinite number of variable abscisses, terminated at the same fixed point at one end, the other end being at any point of the given line or diameter.

When an absciss and its corresponding ordinate are considered together, they are called the co-ordinates of the curve.

In the common parabola, each ordinate PQ has but one absciss, AP; in the ellipse or circle, the ordinate has two abscisses, AP, BP, lying on the opposite sides of it; and in the hyperbola, the ordinate PQ has also two abscisses, but they lie both on the same side of it. That is, in ge-

neral, a line of the second kind, or a curve of the first kind, may have two abscissæ to each ordinate. But a

line of the third order may have three abscissæ to each ordinate; a line of the fourth order may have four; and so on.

The use of the abscissæ is, in conjunction with the ordinates, to express the nature of the curves, either by some proportion or equation including the abscissæ and its ordinate, with some other fixed invariable line or lines. Every different curve has its own peculiar equation, or property, by which it is expressed, and different from all others: and that equation or expression is the same for every ordinate and its abscissæ, whatever point of the curve be taken. So, in the circle, the square of any ordinate is equal to the rectangle of its two abscissæ, or $AP \cdot PB = PQ^2$; in the parabola, the square of the ordinate is equal to the rectangle of the abscissæ and the parameter; in the ellipse and hyperbola, the square of the ordinate is always in a certain constant proportion to the rectangle of the two abscissæ, namely, as the square of the conjugate to the square of the transverse, or as the parameter to the transverse axis; and so other properties in other curves.

When the natures or properties of curves are expressed by algebraic equations, any general abscissa, as AP , is commonly denoted by the letter x , and the ordinate PQ by the letter y ; the other or constant lines being represented by other letters. Then the equations expressing the nature of these curves are as follow; namely, for the

$$\text{circle} \quad - dx - x^2 = y^2, \text{ where } d \text{ is the diameter } AB;$$

$$\text{parabola} \quad - px = y^2, \text{ where } p \text{ is the parameter;}$$

$$\text{ellipse} \quad - t^2 : c^2 :: tx - x^2 : y^2, \quad \{ \text{where } t \text{ is the transverse,}$$

$$\text{hyperbola} \quad t^2 : c^2 :: tx + x^2 : y^2, \quad \{ \text{and } c \text{ the conjugate axis.}$$

But if the abscissæ are taken from the centre; then in the circle $- b^2 - x^2 = y^2$, $\{$ where b is the semiaxis, ellipse $- b^2 : c^2 :: b^2 - x^2 : y^2$, $\{$ where b is the semiaxis, hyperbola $b^2 : c^2 :: x^2 - b^2 : y^2$, $\{$ and c the semiconjugate.

Or we may likewise employ the parameter p in the equation to the ellipse and hyperbola; then in the ellipse $- t : p :: tx - x^2 : y^2$, $\{$ when the abscissæ are taken hyperbola $t : p :: x^2 \pm tx : y^2$, $\{$ from the vertex, ellipse $- t : p :: \frac{x^2}{4} - x^2 : y^2$, $\{$ when the abscissæ are taken hyperbola $t : p :: x^2 - \frac{t^2}{4} : y^2$, $\{$ from the centre, where t is the transverse axis, and p the parameter.

A B S I S, A B S E S, A B S I D E S. See A P S I S, &c.

A B S O L U T E E Q U A T I O N, in Astronomy, is the sum of the optic and eccentric equations. The apparent inequality of a planet's motion, arising from its not being equally

distant from the earth at all times, is called its optic equation; and this would subsist even if the planet's real motion were uniform. The eccentric inequality is caused by the planet's motion being not uniform. To illustrate this, conceive the sun to move, or to appear to move, in the circumference of a circle, in whose centre the earth is placed. It is manifest, that if the sun move uniformly in this circle, he must appear to move uniformly to a spectator at the earth; and in this case there will be no optic nor eccentric equation. But suppose the earth to be placed out of the centre of the circle: then, though the sun's motion should be really uniform, it would not appear to be so, being seen from the earth; and in this case there would be an optic equation, without an eccentric one. But if we imagine the sun's orbit not to be circular, but elliptical, and the earth in its focus; it will be full as evident that the sun cannot appear to have a uniform motion in such ellipse; so that his motion will then be subject to two equations; that is, the optic equation, and the eccentric equation. See EQUATION, and OPTIC INEQUALITY.

A B S O L U T E N U M B E R, in Algebra, is that term or member of an equation that is completely known, and which is equal to all the other, or unknown terms, taken together; and is the same as what Viete calls the homogeneum comparisionis. So, of the equation $x^2 + 16x - 36 = 0$, or $x^2 + 16x = 36$, the absolute number, or known term, is 36.

A B S O L U T E G R A V I T Y, M O T I O N, S P A C E, T I M E, &c. See the respective substantives.

A B S T R A C T M A T H E M A T I C S, otherwise called pure mathematics, is that which treats of the properties of magnitude, figure, or quantity, absolutely and generally considered, without restriction to any species in particular: such as Arithmetic and Geometry. In this sense, abstract, or pure mathematics, is opposed to mixed mathematics, in which simple and abstract properties, and the relations of quantities, primitively considered in pure mathematics, are applied to sensible objects; as in astronomy, hydrostatics, optics, &c.

A B S T R A C T N U M B E R, is a number, or collection of units, considered in itself, without being applied to denote a collection of any particular and determinate things. So, for example, 3 is an abstract number, so far as it is not applied to something: but when we say 3 feet, or 3 persons, the 3 is no longer an abstract, but a concrete number.

A B S U R D, or A B S U R D U M, a term commonly used in demonstrating converse propositions; a mode of demonstration, in which the proposition intended is not proved in a direct manner, by principles before laid down; but it proves that the contrary is absurd or impossible; and so indirectly, as it were, proves the proposition itself. The 4th proposition in the first book of Euclid, is the first in which he makes use of this mode of proof; where he shows that if the extremities of two lines coincide, those lines will coincide in all their parts, otherwise they would inclose a space, which is absurd, or contrary to the 10th axiom. Most converse propositions are proved in this way, which mode of proof is called *reductio ad absurdum*.

A B U N D A N T N U M B E R, in Arithmetic, is a number whose aliquot parts, added all together, make a sum which is greater than the number itself. Thus 12 is an abundant number, because its aliquot parts, namely 1, 2,

3, 4, 6, when added together, make 16, which is greater than the number 12 itself.

An abundant number is opposed to a deficient one, which is less than the sum of its aliquot parts taken together, as the number 14, whose aliquot parts, 1, 2, 7, make no more than 10; and to a perfect number, which is exactly equal to the sum of all its aliquot parts, as the number 6, which is equal to the sum of 1, 2, 3, its aliquot parts.

ACADEMICIAN, a member of a society called an academy, instituted for the promotion of arts, sciences, or natural knowledge in general.

ACADEMICS, an ancient sect of philosophers, who followed the doctrine of Socrates and Plato, as to the uncertainty of knowledge, and the incomprehensibility of truth.

Academic, in this sense, amounts to much the same with Platonist; the difference between them being only in point of time. Those who embraced the system of Plato, among the ancients, were called Academic, academician or academic; whereas those who did the same since the restoration of learning, have assumed the denomination of Platonists.

There are usually reckoned three sects of academics; though some make five. The ancient academy was that of which Plato was the chief. Arcessillas, one of Plato's successors, introducing some alterations into the philosophy of this sect, founded what is called the second academy. The establishment of the third, called also the new academy, is attributed to Lacydes, or rather to Carneades. Some authors add a fourth, founded by Philo; and a fifth, by Antiochus, called the Antiochan, which tempered the ancient academy with Stoicism.

The ancient academy doubted of every thing; and carried this principle so far as to make it a doubt, whether or no they ought to doubt. It was a kind of a principle with them, never to be certain or satisfied of any thing; never to affirm or to deny any thing, either for true or false.

The new academy was somewhat more reasonable; they acknowledged several things for truths, but without attaching themselves to any with entire assurance. These philosophers had found that the ordinary commerce of life and society was inconsistent with the absolute and universal doubtfulness of the ancient academy: and yet it is evident that they looked upon things rather as probable, than as true and certain: by this amendment thinking to secure themselves from those absurdities into which the ancient academy had fallen.

ACADEMIST, the same as Academician.

ACADEMY, **ACADEMIA**, in Antiquity, a fine villa or pleasure-house, in one of the suburbs of Athens, about a mile from the city; where Plato, and the wise men who followed him, held assemblies for disputes and philosophical conference; which gave the name to the sect of Academies. The house took its name, Academy, from one Academus, or Eudemus, a citizen of Athens, to whom it originally belonged: he lived in the time of Theseus; and here he used to have gymnastic sports or exercises.

The academy was further improved by Cimon, and adorned with fountains, trees, shady walks, &c, for the convenience of the philosophers and men of learning, who here met to confer and dispute for their mutual improvement. It was surrounded with a wall by Hipparchus,

the son of Pisistratus; and it was also used as the burying-place for illustrious persons, who had deserved well of the republic.

It was here that Plato taught his philosophy; and hence it was that all public places, destined for the assemblies of the learned and ingenious, have been since called Academies.—Sylla sacrificed the delicious walks and groves of the academy, which had been planted by Cimon, to the ravages of war; and employed those very trees in constructing machines to batter the walls of the city which they had adorned.—Cicero too had a villa, or country retirement, near Puzzuoli, which he called by the same name, Academia. Here he used to entertain his philosophical friends; and here it was that he composed his Academical Questions, and his books *De Naturâ Deorum*.

ACADEMY, among the moderns, denotes a regular society or company of learned persons, instituted under the protection of some prince, or other public authority, for the cultivation and improvement of arts or sciences.

Some authors confound Academy with University; but though much the same in Latin, they are very different things in English. An university is properly a body composed of graduates in the several faculties; of professors, who teach in the public schools; of regents or tutors, and students who, learn under them, and aspire likewise to degrees. Whereas, an academy is not intended to teach, or profess any art or science, but to improve it: it is not for novices to be instructed in, but for persons of learning to confer in, and communicate their lights and discoveries to each other, for their mutual benefit and improvement.

The first modern academy we read of, was established by Charlemagne, by the advice of Alcuin, an English monk: it was composed of the most intelligent men of the court, the emperor himself being a member. In their academical conferences, every person was to give some account of the ancient authors he had read; and each one assumed the name of some ancient author, that pleased him most, or some celebrated person of antiquity. Alcuin, from whose letters we learn these particulars, took that of Flaccus, the surname of Horace; a young lord, named Augustib, took that of Homer; Adelard, bishop of Corbie, was called Augustin; Recluse, bishop of Menth, was Dametas; and the king himself, David.

Since the revival of learning in Europe, academies have multiplied greatly, most nations being furnished with several, and from their communications the chief improvements have been made in the arts and sciences, and in cultivating natural knowledge. There are now academies for almost every art, or species of knowledge; but we shall give a short account only of those institutions of this kind, which regard the cultivation of mathematical or philosophical subjects, which are the proper and peculiar objects of our undertaking.

Italy abounds more in academies than any other country; there being enumerated by Jarekius not less than five hundred and fifty; and even to the amount of twenty-five in Milan itself. These are, however, mostly of a private and inferior nature.

The first academy of a philosophical kind was established at Naples, in the house of Baptista Porta, about the year 1560, under the name of *Academia Secretorum Naturae*; being formed for the improvement of natural and mathematical knowledge. This was succeeded by the

ACADEMY of *Lyncei*, founded at Rome by prince Frederick Cesi, towards the end of the same century. It was rendered famous by the notable discoveries made by several of its members; among whom was the celebrated Galileo Galilei.

Several other academies contributed also to the advancement of the sciences; but it was by speculations, rather than by repeated experiments on the phenomena of nature: such were the academy of Bessarian at Rome, and that of Laurence de Medicis at Florence, in the 15th century; and in the 16th those of *Infiammati* at Padua, of *Vegna Juoli* at Rome, of *Ortolani* at Placentia, and of *Umidi* at Florence, were constituted. The first of these studied fire and pyrotechnia; the second, wine and vineyards; the third, pot-herbs and gardens; the fourth, water and hydraulics. To these may be added that of Venice, called *La Veneta*, and founded by Frederick Badara, a noble Venetian; another in the same city, of which *Campogio*, bishop of Feltro, appears to have been the chief; also that of *Coscnza*, or *La Consentina*, of which *Bernadin Telesio*, *Sertorio Quatromani*, *Paulus Aquinas*, *Julio Cavalcanti*, and *Fabio Cicili*, celebrated philosophers, were the chief members. The compositions of all these academies, of the 16th century, were good in their kind; but none of them comparable to those of the *Lyncei*.

ACADEMY *del Cimento*, that is, of Experiments, arose at Florence, some years after the death of Torricelli, namely in the year 1657, under the protection of prince Leopold of Tuscany, afterwards cardinal de Medicis, and brother to the Grand Duke Ferdinand the Second. Galileo, Torricelli, Aggiunti, and Viviani had prepared the way for it: and one of its chief members was *Paul del Buono*, who in 1657 invented the instrument for trying the incompressibility of water, which was a thick globular shell of gold, having its cavity filled with water; the globe being compressed by a strong screw, the water came through the pores of the gold, rather than yield to the strong compression: there were also, Alphonsus Borelli, well known for his ingenious treatise *De Motu Animalium*, and other works; *Candide del Buono*, brother of *Paul*; Alexander Marsilli, *Vincenzi Viviani*, *Francis Rhedi*, and the Count Laurence Magalotti, secretary of the academy, who published a volume of their curious experiments in 1667, under the title of *Saggi di Naturali Esperienze*; a copy of which being presented to the Royal Society, it was translated into English by Mr. Waller, and published at London, in 4to, 1684: being *A curious collection of tracts, containing ingenious experiments on the pressure of the air, on the compressing of water, on cold, heat, ice, magnets, electricity, odours, the motion of sound, projectiles, light, &c, &c.* But we have heard little or nothing more of the academy since that time. It may not be improper to observe here, that the Grand Duke Ferdinand, above mentioned, was himself no mean philosopher and chemist, and that he invented thermometers, of which the construction and use may be seen in the collection of the academy *del Cimento*.

ACADEMY *degli Inquieti*, at Bologna, incorporated afterwards into that della traccia in the same city, followed the example of that *del Cimento*. The members met at the house of the abbot Antonio Sampieri; and here *Geminiano Montanari*, one of the chief members, made excellent discourses on mathematical and philosophical subjects, some parts of which were published in 1667, under

the title of *Pensieri Fisico-Mathematici*. This academy afterwards met in an apartment of Eustachio Manfredi; and then in that of Jacob Sandri; but it arrived at its chief lustre while its assemblies were held in the palace Marsilli.

ACADEMY of *Rossano*, in the kingdom of Naples, called *La Societa Scientifica Rossanese degl' Incuriosi*, was founded about the year 1540, under the name of *Naviganti*; and was renewed under that of *Spensierati*, by *Camillo Tuscano*, about the year 1600. It was then an academy of belles-lettres; but was afterwards transformed into an academy of sciences, on the solicitation of the learned abbot *Don Giacinto Gimma* who, being made president under the title of promoter-general, in 1695, gave it a new set of regulations. He divided the academicians into several classes, namely, grammarians, rhetoricians, poets, historians, philosophers, physicians, mathematicians, lawyers, and divines; with a separate class for cardinals and persons of quality. To be admitted a member, it was necessary that the candidate should have degrees in some faculty. Members, in the title of their books, are not allowed to use the name *Academist* without a written permission from the president, which is not granted till the work has been examined by the censors of the academy. This permission is the highest honour the academy can confer; since they hereby, as it were, adopt the work, and engage to answer for it against any criticisms that may be made upon it. The president himself is not exempt from this law: nor is any academician permitted to publish any thing against the writings of another, without leave obtained from the society.

There have been several other academies of sciences in Italy, but they have not long subsisted, for want of the support of the reigning princes. Such were at Naples that of the *Investiganti*, founded about the year 1679, by the marquis d'Arena, *Don Andrea Concubletto*; and that which, about the year 1698, met in the palace of *Don Lewis della Cerda*, the duke de Medina, and viceroy of Naples; at Rome, that of *Fisico-Matematici*, which in 1686 met in the house of *Sigñor Ciampini*; at Verona, that of *Atelofili*, founded the same year by *Sigñor Joseph Gazola*, and which met in the house of the count Serenghi della Cucca; at Brescia, that of *Filesoiici*, founded the same year for the cultivation of philosophy and mathematics, and terminated the year following: that of *F. Francisco Lana*, a jesuit of great skill in these sciences: and lastly, that of *Fisico-Critici* at Sicna, founded in 1691, by *Sigñor Peter Maria Gabrielli*.

Some other academies, still or lately subsisting in Italy, repair with advantage the loss of the former. One of the principal is the academy of *Filarmonici* at Verona, supported by the marquis *Scipio Maffei*, one of the most learned men in Italy; the members of which academy, though they cultivate the belles-lettres, do not neglect the sciences. The academy of *Ricovrati* at Padua still subsists with reputation; in which, from time to time, learned discourses are held on philosophical subjects. The like may be said of the academy of the *Muti di Reggio*, at Modena. At Bologna is an academy of sciences, in a flourishing condition, known by the name of *The Institute of Bologna*; which was founded in 1712 by count *Marsigli*, for cultivating physics, mathematics, medicine, chemistry, and natural history. The history of it is written by *M. de Limiers*, from memoirs furnished by the founder himself. Among the new academies, that which ranks

first, after the Institute of Bologna, is given to that of the Countess Donna Clelio Grillo Borromeo, one of the most learned ladies of the age, to whom Signor Gimma dedicates his literary history of Italy. She had lately established an academy of experimental philosophy in her palace at Milan; of which Signor Vallisnieri was nominated president, and had already drawn up the regulations for it, though we do not find it has ever taken place. In the number of these academies may also be ranked the assembly of the learned, who of late years met at Venice in the house of Signor Cristino Martinelli, a noble Venetian, and a great patron of learning.

ACADEMIA *Cosmografica*, or that of the Argonauts, was instituted at Venice, at the instance of F. Coronelli, for the improvement of geography; the design being to procure exact maps, geographical, topographical, hydrographical, and ichnographical, of the celestial as well as terrestrial globe, and their several regions or parts, together with geographical, historical, and astronomical descriptions, accommodated to them: to promote which purposes, the several members oblige themselves, by their subscription, to take one copy or more of each piece published under the direction of the academy; and to advance the money, or part of it, to defray the charge of publication. To this end three societies were settled, namely at Venice, Paris, and Rome; the first under F. Moro, provincial of the Minorites of Hungary; the second under the abbot Laurence au Rue Payenne au Marais; the third under F. Ant. Baldigiani, jesuit, professor of mathematics in the Roman college; to whom those addressed themselves who were willing to engage in this design. The Argonauts numbered near 200 members, in the different countries of Europe; and their device is the terraqueous globe, with the motto *Plus ultra*. All the globes, maps, and geographical writings of F. Coronelli have been published at the expense of this academy.

THE ACADEMY of *Apatisis*, or Impartial Academy, deserves to be mentioned on account of the extent of its plan, including universally all arts and sciences. It holds from time to time public meetings at Florence, where any person, whether academician or not, may read his works, in whatever form, language, or subject; the academy receiving all with the greatest impartiality.

In France there are many academies for the improvement of arts and sciences. F. Mersenne, it is said, gave the first idea of a philosophical academy in France, about the beginning of the seventeenth century, by the conferences of mathematicians and naturalists, held occasionally at his lodgings; at which Des Cartes, Gassendus, Hobbes, Roberval, Pascal, Blondel, and others, assisted. F. Mersenne proposed to each of them certain problems to examine, or certain experiments to be made. These private assemblies were succeeded by more public ones, formed by M. Monmort, and M. Thevenot, the celebrated traveller. The French example animated several Englishmen of rank and learning to erect a kind of philosophical academy at Oxford, towards the close of Cromwell's administration; which after the restoration was erected, by public authority, into a Royal Society: an account of which see under the word. The English example, in its turn, animated the French. In 1666 Louis XIV, assisted by the counsels of M. Colbert, founded an academy of sciences at Paris, called The

ACADEMIE *Royale des Sciences*, or *Royal Academy of Sciences*, for the improvement of philosophy, mathema-

tics, chemistry, medicine, belles-lettres, &c. Among the principal members, at the commencement in 1666, were the respectable names of Carcavi, Huygens, Roberval, Frenicle, Auzout, Picard, Buot, Du Hamel the Secretary, and Mariotte. There was a perfect equality among all the members, and many of them received salaries from the king. By the rules of the academy, every class was to meet twice a week; the philosophers and geometers were to meet, separately, every Wednesday, and then both together on the Saturday, in a room of the king's library, where the philosophical and mathematical books were kept: the history class was to meet on the Monday and Thursday, in the room of the historical books; and the class of belles-lettres on the Tuesday and Friday: and on the first Thursday of every month all the classes met together, and by their secretaries made a mutual report of what had been transacted by each, during the preceding month.

In 1699, on the application of the president, the abbé Bignon, the academy received, under royal authority and protection, a new form and constitution; by the articles of which, the academy was to consist of four sorts of members, namely honorary, pensionary, associates, and élèves. The honorary class to consist of ten persons, and the other three classes of twenty persons each. The president to be chosen annually out of the honorary class, and the secretary and treasurer to be perpetual, and of the pensionary class. The meetings to be twice a week, on the Wednesday and Saturday; besides two public meetings in the year.

Of the pensionaries, or those who receive salaries, three to be geometers, three astronomers, three mechanists, three anatomists, three botanists, and three chemists, the other two being the secretary and treasurer. Of the twenty associates, of which twelve to be French, and eight might be foreigners, two were to cultivate geometry, two astronomy, two mechanics, two anatomy, two botany, and two chemistry. Of the twenty élèves, one to be attached to each pensionary, and to cultivate his peculiar branch of science. The pensionaries and their élèves to reside at Paris. No regulars nor religious to be admitted, except into the honorary class; nor any person to be admitted a pensioner who was not known by some considerable work, or some remarkable discovery.

In 1716 the Duke of Orleans, then regent of France, by the king's authority made some alteration in their constitution. The class of élèves was suppressed; and instead of them were instituted twelve adjuncts, two to each of the six classes of pensioners. The honorary members were increased to twelve: and a class of six free associates was made, who were not under the obligation of cultivating any particular branch of science, and in this class only could the regulars or religious be admitted. A president and vice-president to be appointed annually from the honorary class, and a director and sub-director annually from that of the pensioners. And no person to be allowed to make use of his quality of academician, in the title of any of his books that he published, unless such book were first approved by the academy. The academy had for a device or motto, *Invenit et perficit*. And the meetings, which were formerly held in the king's library, since the year 1699 were held in a fine hall of the old Louvre.

Finally, in the year 1785, the king confirmed, by letters patent, dated April 23, the establishment of the aca-

demy of sciences, making the following alterations, and adding classes of agriculture, natural history, mineralogy, and physics; incorporating the associates and adjuncts, and limiting the number of members to six each class, namely three pensioners and three associates; by which the former received an increase of salary, and the latter approached nearer to becoming pensioners.

By the articles of this instrument it was ordained, that the academy shall consist of eight classes, 1st geometry, 2^d astronomy, 3^d mechanics, 4th general physics, 5th anatomy, 6th chemistry and metallurgy, 7th botany and agriculture, and 8th natural history and mineralogy. That each class shall remain irrevocably fixed at six members; namely, three pensioners and three associates, independent however of a perpetual secretary and treasurer; of twelve free-associates and of eight associate strangers or foreigners, the same as before, except that the adjunct-geographer for the future to be called the associate-geographer.

The classes at first to be filled by the following persons, namely, that of geometry by Messieurs de Borda, Jeaurat, Vandermonde, as pensioners; and Messieurs Cousin, Meusnier, and Charles, as associates: that of astronomy by Messieurs le Monnier, de la Lande, and le Gentil, as pensioners; and Messieurs Messier, de Cassini, and Dabegat, as associates: that of mechanics by Messieurs l'abbé Bossut, l'abbé Rochon, and de la Place, as pensioners; and Messieurs Coulomb, le Gendre, and Perrier, as associates: that of general physics by Messieurs Leroy, Brisson, and Bailly, as pensioners; and Messieurs Monge, Mechain, and Quatremere, as associates: that of anatomy by Messieurs Daublton, Tenon, and Portal, as pensioners; and Messieurs Sabatier, Vicq-d'azir, and Broussonet, as associates: that of chemistry and metallurgy by Messieurs Cadet, Lavoisier, and Beaume, as pensioners; and Messieurs Cornette, Berthollet, and Fourcroy, as associates: that of botany and agriculture by Messieurs Guettard, Fougroux, and Adanson, as pensioners; and Messieurs de Jussieu, de la Marck, and Desfontaines, as associates: and that of natural history and mineralogy by Messieurs Desmaretz, Saye, and l'abbé de Gua, as pensioners; and Messieurs Darct, l'abbé Hauy, and l'abbé Tessier, as associates. All names respectable in the commonwealth of letters; and from whom the world might expect still further improvements in the several branches of science.

The late M. Rouille de Meslay, counsellor of the parliament of Paris, founded two prizes, the one of 2500 livres, the other of 2000 livres, which the academy distributed alternately every year: the subjects of the former prize respecting physical astronomy; and of the latter, navigation and commerce.

The world is highly indebted to this academy for the many valuable works they have executed, or published, both individually and as a body collectively, especially by their memoirs, making upwards of hundred volumes in 4^{to}, with the machines, indexes, &c. in which may be found most excellent compositions in every branch of science. They published a volume of these memoirs every year, with the history of the academy, and elegies of remarkable men lately deceased: also a general index to the volumes every ten years. An alteration was introduced into the volume for 1783, which it seems was to be continued in future, by omitting, in the history, the minutes or extracts from the registers, containing some

preliminary account of the subjects of the memoirs; but still however retaining the eleges of distinguished men, lately deceased.

M. l'abbé Rozier also published, in four quarto volumes, an excellent index of the contents of all the volumes, and the writings of all the members, from the beginning of their publications to the year 1770; with convenient blank spaces for continuing the articles in writing.

Their history also, to the year 1697, was written by M. Du Hamel; and after that time continued from year to year by M. Fontenelle, under the following titles, *Du Hamel Historia Regiae Academie Scientiarum, Paris, 4^{to}. Histoire de l'Academie Royale des Sciences, avec les Mémoires de Mathematique et de Physique, tirez des Registres de l'Academie, Paris, 4^{to}. Histoire de l'Academie Royale des Sciences depuis son établissement en 1666, jusqu'en 1699, en 13 tomes, 4^{to}.* A new history, from the institution of the academy, to the period from whence M. de Fontenelle commences, has been formed; with a series of the works published under the name of this academy, during the first interval.

The French revolution, however, gave occasion to the new-modeling of the Academy in 1793, as well as an alteration in its name. (See INSTITUTE.) The memoirs of the academy are comprehended in 139 volumes, 4^{to}; viz; 11 vols. from its foundation in 1666, to its renewal in 1699; 92 vols. from 1699 to 1790; 11 vols. of memoirs presented to the academy, 9 vols. of prizes, 9 of tables, and 7 of drawings of machines.

Besides the academies in the capital, there were a great many in other parts of France. The

ACADEMIE Royale, at Caen, was established by letters patent in the year 1705; but it had its rise fifty years earlier, in private conferences, held first in the house of M. de Brieux. M. de Segrais retiring to this city, to spend the rest of his days, restored and gave new lustre to their meetings. In 1707 M. Foucault, intendant of the generality of Caen, procured the king's letters patent for erecting them into a perpetual academy, of which M. Foucault was to be protector for the time, and the choice afterwards left to the members, the number of whom was fixed to thirty, chosen for this time by M. Foucault. But besides the thirty original members, leave was given to add six supernumerary members, from the ecclesiastical communities in that city.

At Toulouse was the *Academie des jeux floraux*, composed of forty persons, the oldest of the kingdom: besides an academy of sciences and belles-lettres, founded in 1750.

At Montpelier, the royal society of sciences; which, after 1708, was united with the royal academy of sciences at Paris.

Other academies were also established: at Bourdeaux, founded in 1703; at Soissons in 1674, at Marseilles in 1726, at Lyons in 1700, at Pau in Bearn in 1721, at Montauban in 1744, at Angers in 1685, at Amiens in 1750, at Villefranche in 1679, at Dijon in 1740, at Nîmes in 1682, at Besançon in 1752, at Chalons in 1775, at Rochelle in 1734, at Beziers in 1723, at Rouen in 1744, at Metz in 1760, at Arras in 1773, &c. The number of these academies is continually augmenting; and even in such towns as have no academies, the literati form themselves into literary societies, having nearly the same objects and pursuits.

In Germany and other parts of Europe there are various academies of sciences, &c. The

ACADEMIE *Royale des Sciences et des Belles-Lettres* of Prussia, was founded at Berlin, in the year 1700, by Frederic I. king of Prussia, of which the celebrated M. Leibnitz was the first president, and its great promoter. The academy received a new form and a new set of statutes in 1710; by which it was ordained, that the president shall be one of the counsellors of state; and that the members be divided into four classes; the first to cultivate physics, medicine, and chemistry; the second, mathematics, astronomy, and mechanics; the third, the German language, and the history of the country; and the fourth, oriental learning, particularly as it may concern the propagation of the gospel among infidels. That each class elect a director for themselves, who shall hold his post for life. That they meet in the castle called the New Marshal, the classes to meet in their turns, one each week. And that the members of any of the classes have free access into the assemblies of the rest. Several volumes of their transactions have been published in Latin, from time to time, under the title of *Miscellanea Berolinensis*.

In 1743 Frederic II. king of Prussia made great alterations and improvements in the academy. Instead of a great lord or minister of state, who had usually presided over the academy, he wisely judged that office would be better filled by a man of letters; and he honoured the French academy of sciences by fixing upon one of its members for a president, namely M. Maupertuis, a distinguished character in the literary world, and whose conduct in improving the academy was a proof of the sound judgment of the king, who at the same time made new regulations for the academy, and took the title of its Protector. From that time the transactions of the academy have been published annually, under the title of *Histoire de l'Academie Royale des Sciences et Belles Lettres à Berlin*, much in the manner of those of the French academy of sciences, and in the French language; particularly enriched with the compositions of the celebrated Euler, and other learned men. Besides the ordinary private meetings of the academy, it has two public ones in the year, in January and May; at the latter of which is given a prize gold medal, of the value of 50 ducats, or about 20 guineas. The subject of the prize is successively physics, mathematics, metaphysics, and general literature. For the academy has this peculiar circumstance, that it embraces also metaphysics, logic, and morality; having one class particularly appropriated to these objects, called the class of Speculative Philosophy.

Imperial ACADEMY of Petersburg. This academy was projected by the czar Peter I, commonly called Peter the Great, who in so many other instances also was instrumental in raising Russia from the state of barbarity in which it had been immersed for so many ages. Having visited France in 1717, and among other things informed himself of the advantages of an academy of arts and sciences, he resolved to establish one in his new capital, whether he had drawn by noble encouragements several learned strangers, and made other preparations, when his death prevented him from fully accomplishing that object, in the beginning of the year 1725. Those preparations and intentions however were carried into execution the same year, by the establishment of the academy, by his consort the czarina Catharine, who succeeded him.

And soon after the academy composed the first volume of their works, published in 1728, under the title of *Commentarii Academici Scientiarum Imperialis Petropolitanae*; which they continued almost annually till 1746, the whole amounting to 14 volumes, which were published in Latin, and the subjects divided and classed under the following heads, namely mathematics, physics, history, and astronomy. Their device a tree bearing fruit not ripe, with the modest motto *Paullatim*.

Most part of the strangers who composed this academy being dead, or having retired, it was rather in a languishing state at the beginning of the reign of the empress Elizabeth, when the count Rasomowski was happily appointed president, who was instrumental in recovering its vigour and labours. This empress renewed and altered its constitution, by letters patent dated July 24, 1747, giving it a new form and regulations. It consists of two chief parts, an academy, and a university, having regular professors in the several faculties, who read lectures as in our colleges. The ordinary assemblies are held twice a week, and public or solemn once thrice in the year; in which an account is given of what has been done in the private ones. The academy has a noble building for their meetings, &c, with a good apparatus of instruments, a fine library, observatory, &c. Their first volume, after this renovation, was published for the years 1747 and 1748, and they have been since continued from year to year, now to a great number of volumes, under the title of *Novi Commentarii Academici Scientiarum Imperialis Petropolitanae*. They are printed in the Latin language, and contain many excellent compositions in all the sciences, especially the mathematical papers of the late excellent M. L. Euler, which always made a considerable portion of every volume. The subjects are classed under heads in the following order, mathematics, physicomathematics, physics, which include botany, anatomy, &c, and astronomy; the whole prefaced by historical extracts, or minutes, relating to each paper or memoir, after the manner of the volumes of the French academy; but wanting however the eloges of deceased eminent men. Their device is a heap of ripe fruits piled on a table, with the motto *En addit Fructus astate recentes*. After the death of Euler, in 1783, who had been many years the president, that important literary office was, by the empress Catharine, conferred on the princess Daschikof.

Imperial and Royal ACADEMY of Sciences and Belles-Lettres, at Brussels. This academy was founded in the year 1773; and several volumes of their memoirs have been published.

Royal ACADEMY of Sciences, at Stockholm, was instituted in 1739, and since that time it has published a great many volumes of transactions, quarterly, in Svo, in the Swedish language.

For an account of the Royal Society of London, and several other similar institutions, see the words JOURNAL, SOCIETY, &c.

American ACADEMY of Arts and Sciences, was established in 1780 by the council and house of representatives in the province of Massachusetts's Bay, for promoting the knowledge of the antiquities of America, and the natural history of the country; for determining the uses to which its various natural productions may be applied; for encouraging medicinal discoveries, mathematical disquisitions, philosophical inquiries and experiments, astronomical, meteorological, and geographical observations,

and improvements in agriculture, manufactures, and commerce; and, in short, for cultivating every art and science, which may tend to advance the interest, honour, dignity, and happiness, of a free, independent, and virtuous people. The members of this academy are never to be less than forty, nor more than two hundred.

ACADEMY is also used among us for a kind of collegiate school, or seminary; where youth are instructed in the liberal arts and sciences in a private way: now indeed it is used for all kinds of schools.

Frederic I, king of Prussia, established an academy at Berlin in 1703, for educating the young nobility of the court, suitable to their extraction. The expence of the students was very moderate, the king having undertaken to pay the extraordinaries. This illustrious school, which was then called the academy of princes, has now lost much of its first splendour.

The Romans had a kind of military academies established in all the cities of Italy, under the name of Campi Martis. Here the youth were admitted to be trained for war at the public expence. And the Greeks, besides academies of this kind, had military professors, called Tactici, who taught all the higher offices of war, &c.

We have three royal academies of this kind in England, the expenses of which are defrayed by the government; the one at Woolwich, for the artillery and military engineers; another at Portsmouth, for the navy; and the third at Sandhurst near Bagshot, called the Royal Military College, for educating officers for the army in general. (See COLLEGE.) The first was established by his majesty King George II, by warrants dated April the 30th and November the 18th, 1741, for instructing persons belonging to the military part of the ordnance, in the several branches of mathematics, fortification, &c, proper to qualify them for the service of artillery and the office of engineers. This institution under the direction of the master-general and board of ordnance for the time being: and at first the lectures of the masters in the academy were attended by the practitioner-engineers, with the officers, serjeants, corporals, and private men of the artillery, besides the cadets. At present, however, none are educated there but the gentlemen cadets, to the number of 180. The master-general of the ordnance is always captain of the cadets' company, and governor of the academy; under him are a lieutenant-governor, and an inspector of studies. The masters have been gradually increased, from two or three at first, now (in 1814) to almost twenty; namely, a professor of mathematics; and six or seven other mathematical masters, a professor of fortification, and two assistants, two drawing-masters, two French masters, with masters for fencing, dancing, and chemistry. This institution is of the greatest consequence to the state, and it is hardly credible that so important an object should be accomplished at so trifling an expense.

The Royal Naval Academy at Portsmouth was founded by George I, in 1722, for instructing young gentlemen in the sciences useful for navigation, to educate them for the royal navy. The establishment is under the direction of the board of admiralty, who give salaries to the different masters, by one of whom the students are boarded and lodged, the expense of which is defrayed by their own friends, nothing being supplied by the government but their education.—This academy has been lately new-modelled, and its name changed to the Royal Naval College. See COLLEGE.

ACANTHUS, in Architecture, the leaves of a plant which forms the ornament of the capital of the Corinthian order. See ABACUS.

ACCELERATED Motion, is that which receives fresh accessions of velocity; and the acceleration may be either equable or variable: if the accessions of velocity be always equal in equal times, the motion is said to be equably or uniformly accelerated: but if the accessions, in equal times, either increase or decrease, then the motion is unequably or variably accelerated.

Acceleration is directly opposite to retardation, which denotes a diminution of velocity.

Acceleration comes more particularly under consideration in physics, in respect to the descent of heavy bodies, falling freely towards the centre of the earth.

That bodies are accelerated in their descent is evident from various circumstances, which immediately strike the eye of an attentive observer: thus, the greater the height from whence a body falls, the greater impression it makes on the object upon which it impinges; and this increase of action upon the fixed body, must necessarily arise from an increase of velocity in the moving one, or from its acceleration. Before the law of gravitation was known, which is now generally acknowledged to be the immediate cause of the acceleration of bodies, various fantastical hypotheses were advanced to account for this phenomenon; some ascribing it to the action of the atmosphere; others to a very subtle fluid, which they introduced for that particular purpose; others again, attributed it to a kind of instinct in bodies, by means of which they accelerated their motion as they approached towards the centre of the earth, that being considered as the place appropriated to their element: these and various other hypotheses of a similar nature are now entirely rejected, and would be wholly unworthy of being mentioned, did they not serve to show how much the knowledge of man is increased, and the solid foundation upon which the modern philosophy is established, when compared with the vague and hypothetical theories of the ancients.

Leaving therefore all such visionary causes of acceleration, and only admitting the existence of such a force as gravity, so evidently inherent in all bodies, without regard to what may be the cause of it, the whole mystery of acceleration will be cleared up. Consider gravity then, with Galileo, only as a cause or force which acts continually on heavy bodies; and it will be easy to conceive that the force of gravitation, which determines bodies to descend, must by a necessary consequence accelerate them in falling.

A body then having once begun to descend, by the impulse of gravity will continue to descend by Newton's first law of nature, even though the first cause of its descent should cease. But besides this determination to move, impressed upon it by the first cause of motion, and which would be sufficient to continue to infinity the degree of motion already begun, new impulses are continually superadded by the same cause; which continues to act upon the body already in motion, in the same manner as if it had remained at rest. There being now then two causes of motion, acting both in the same direction; it necessarily follows, that the motion which they unitedly produce, must be more considerable than that which either could produce separately. And as long as the motion is thus continued, the same cause still operating to increase it, the descent must necessarily be continually accelerated.

Supposing then that gravity, from whatever principle it arises, acts uniformly upon all bodies at the same distance from the centre of the earth; and conceive the time which a heavy body takes in falling to the earth, to be divided into indefinitely small equal parts; gravity will impel the body toward the centre, in the first indefinitely short instant of the descent; and if after this we suppose the action of gravity to cease, the body will continue perpetually to advance uniformly toward the earth's centre, with an indefinitely small velocity, equal to that which resulted from the first impulse.

But if we suppose that the action of gravity still continues the same after the first impulse; in the second instant, or small part of time, the body will receive a new impulse toward the earth, equal to that which it received in the first instant; and consequently its velocity will be doubled; in the third instant, it will be tripled; in the fourth, quadrupled; in the fifth, quintupled; and so on continually: for the impulse made in any preceding instant, is in no ways altered by that which is made in the following one; but they are, on the contrary, always accumulated on each other.

So that the instants of time being supposed indefinitely small, and all equal, the velocity acquired by the falling body, will be, at every instant, proportional to the times from the beginning of the descent; and consequently the velocity will be proportional to the time in which it is produced. So that if a body, by this constant force, acquire a velocity of $32\frac{1}{2}$ feet in one second of time; it will acquire a velocity of $64\frac{1}{2}$ feet in 2 seconds, $96\frac{1}{2}$ feet in 3 seconds, $128\frac{1}{2}$ in 4 seconds, and so on. Further, all bodies, great or small, acquire, by the force of gravity, the same velocity in the same time. For every equal particle of matter being endued with an equal impelling force, namely its gravity or weight, the sum of all the forces, in any compound mass of matter, will be proportional to the sum of all the weights, or quantities of matter to be moved; consequently, the forces and masses moved, being thus constantly increased in the same proportion, the velocities generated will be the same in all bodies, great or small. That is, a double force moves a double mass of matter, with the same velocity that the single force moves the single mass; and so on. Or otherwise, the whole compound mass falls all together with the same velocity, and in the same manner, as if its particles were not united, but as if each fell by itself, separated all from one another. And thus all being let go at once, they would fall together, just as if they were united into one mass.

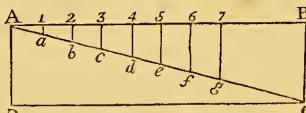

The foregoing law of the descent of falling bodies, namely, that the velocities are always proportional to the times of descent, as well as the following laws concerning the spaces passed over, &c, were first discovered and taught by the great Galileo, and that nearly in the following manner.

Because the constant velocity with which any body moves, or the space it passes over in a given time, as suppose one second, being multiplied by the time, or number of seconds it is in motion, expresses the space passed over in that time; and the area or space of a rectangular figure being denoted by the length multiplied by the breadth; therefore the space so run over, may be considered as a rectangle compounded of the time and velocity, that is a rectangle of which the time denotes the length, and the velocity the breadth. Suppose then A to

be the heavy body which descends, and A B to denote the whole time of its descent; which let be divided into a certain number of equal parts, denoting intervals or portions of the given time, as A C, C D, D E, &c; and imagine the body to descend, during the time expressed by the first of the divisions A C, with a certain uniform velocity arising from the force of gravity acting on it, which let be denoted by A F, the breadth of the rectangle C F; then the space run through during the time denoted by A C, with the velocity denoted by A F, will be expressed by the rectangular space C F.

Now the action of gravity having produced, in the first moment, the velocity A F, in the body, before at rest; in the first two moments it will produce the velocity C G, the double of the former; in the third moment, to the velocity C G will be added one degree more, by which means will be produced the velocity D H, triple of the first; and so of the rest; so that, during the whole time A B, the body will have acquired the velocity B K. Hence, taking the divisions of the line A B at pleasure; for example, the divisions A C, C D, &c, for the times; the spaces run through during those times, will be as the areas or rectangles C F, D G, &c; and so the space described by the moving body during the whole time A B, will be equal to all the rectangles, that is, equal to the whole indented space A B K I H G F. And thus it would happen if the increments of velocity were produced at the end of certain portions of time; for instance at C, D, &c; so that the degree of motion remains the same to the instant that a new acceleration takes place.

By conceiving the divisions of time to be shorter, for example but half as long as the former, the indentures of the figure will be proportionably more contracted, and it will approach nearer to a triangle; and if these divisions be supposed infinitely small, that is, if increments of the velocity be supposed to be acquired continually, and at each indivisible particle of time, which is really the case, the rectangles so successively produced, will form a triangle, as A B C; the whole time A B consisting of minute portions A 1, 2, 3, 4, 5, 6, 7, &c; and the area of the triangle

A B C, of all the minute surfaces, or trapeziums, which answer to the divisions of the times; the area of the whole triangle A B C, will denote the space run through during the whole time A B; and the area of any smaller triangle A 7 g, denoting the space run through during the corresponding time A 7. But the triangles A 1 a, A 7 g, &c, being similar, have their areas to each other as the squares of their like sides A 1, A 7, &c; and consequently the spaces gone through, in any times counted from the beginning, are to each other as the squares of the times.

Hence, in any right-angled triangle, as A B C, the one side A B represents the time, the other side B C the velocity acquired in that time, and the area of the triangle the space described by the falling body.

From the preceding demonstration is also drawn this other general theorem, in motions that are uniformly accelerated; namely, that a body descending with a uniformly accelerated motion, describes in the whole time of its descent, a space, which is exactly the half of that which it would describe uniformly in the same time, with the velocity it has acquired at the end of its accelerated fall. For it has been shown that the whole space which the falling body has run through in the time $A B$, is represented by the triangle $A B C$; the last velocity being $B C$; and the space which the body would run through uniformly in the same time $A B$, constantly with the said greatest velocity $B C$, is represented by the rectangle $A B C D$: but it is well known that the rectangle $A B C D$ is double the triangle $A B C$; and therefore the latter space run through, is double the former; that is, the space run through by the accelerated motion, is just half of that which the body would describe in the same time, moving uniformly with its last-acquired velocity.

Hence then, from the foregoing considerations are deduced the following general laws of uniformly accelerated motions, namely,

1st. That the velocities acquired, are constantly proportional to the times; in a double time a double velocity, &c.

2d. That the spaces described in the whole times, each counted from the commencement of the motion, are proportional to the squares of the times, or to the squares of the velocities; that is, in twice the time, the body will describe 4 times the space; in thrice the time, it will describe 9 times the space; in quadruple the time, 16 times the space; and so on. In short, if the times are proportional to the numbers - 1, 2, 3, 4, 5, &c., the spaces will be as 1, 4, 9, 16, 25, &c., which are the squares of the former. So that, if a body, by the natural force of gravity, fall through the space of $16\frac{1}{2}$ feet in the first second of time; then in the first 2 seconds of time it will fall through 4 times as much, or 64 $\frac{1}{2}$ feet; in the first 3 seconds it will fall 9 times as much, or $144\frac{1}{2}$ feet; and so on. And as the spaces fallen through are as the squares of the times, or of the velocities; therefore the times, or the velocities, are proportional to the square roots of the spaces.

3d. The spaces described by falling bodies, in a series of equal instants or intervals of time, will be as the odd numbers - 1, 3, 5, 7, 9, &c., which are the differences of } 1, 4, 9, 16, 25, &c., the squares or whole spaces } that is, the body which has run through $16\frac{1}{2}$ feet in the first second, will in the next second run through $48\frac{1}{2}$ feet, in the third second $80\frac{1}{2}$, and so on.

4th. A body having fallen through any space in a certain time, it will have acquired a velocity equal to double that space; that is, in an equal time, with the last velocity acquired, if uniformly continued, it would pass over just double the space. So, if a body fall through $16\frac{1}{2}$ feet in the first second of time, it acquires a velocity of $32\frac{1}{2}$ feet in a second; that is, if the body move uniformly for one second, with the velocity acquired, it will pass over $32\frac{1}{2}$ feet in this one second: and if in any time the body fall through 100 feet; then in another equal time, if it move uniformly with the last acquired velocity, it will pass over 200 feet. And so on.

But, as the method of demonstration used by Galileo, by means of infinitely small parts forming a regular tri-

angle, though very ingenious, is not so elegant as might be wished, the areas of triangles being rather unnatural representations of the spaces descended by falling bodies; the same may be otherwise demonstrated thus: Let the whole time of a body's free descent be divided into any number of parts, calling each of these parts t ; and let a denote the velocity acquired at the end of the first part of time; then will $2a$, $3a$, $4a$, &c., represent the velocities at the end of the 2d, 3d, 4th, &c., part of time, because the velocities are as the times; and for the same reason $\frac{1}{2}a$, $\frac{2}{3}a$, $\frac{3}{4}a$, &c., will be the velocities at the middle point of the first, second, third, &c., part of time. But now as the velocities increase uniformly, the space described in any one of these parts of time, may be considered as uniformly described with its middle velocity, or the velocity in the middle of that part of time; and therefore, multiplying those mean velocities each by their common time t , we have the same ratios $\frac{1}{2}a$, $\frac{2}{3}a$, $\frac{3}{4}a$, &c., for the spaces passed over in the successive parts of the time; that is, the space $\frac{1}{2}a$ in the first time, $\frac{2}{3}a$ in the second, $\frac{3}{4}a$ in the third, and so on; then add these spaces successively to one another, and we obtain $\frac{1}{2}a$, $\frac{2}{3}a$, $\frac{3}{4}a$, $\frac{16}{15}a$, &c., for the whole spaces described from the beginning of the motion, to the end of the first, second, third, &c., portion of time; namely $\frac{1}{2}a$ space in one time, $\frac{2}{3}a$ in 2 times, $\frac{3}{4}a$ in 3 times, and so on: and it is evident that these spaces are as the numbers 1, 4, 9, 16, &c., which are as the squares of the times.

And from this mode of demonstration, all the properties above-mentioned evidently following; i. e. the whole spaces - $\frac{1}{2}a$, $\frac{2}{3}a$, $\frac{3}{4}a$, &c., are as the squares of the times - 1, 2, 3, &c., that the separate spaces - $\frac{1}{2}a$, $\frac{2}{3}a$, $\frac{3}{4}a$, &c., described in the successive times, } 1, 3, 5, &c., are as the odd numbers } and that the velocity a acquired in any time 1, is double the space - $\frac{1}{2}a$ described in the same time.

As the laws of acceleration are very important, I shall here insert the two following propositions, sent me by my learned friend Mr. Abram Robertson, of Christ Church College, Oxford, in which those laws are demonstrated in a manner somewhat different.

"PROPOSITION I.—If from the point P in the straight line $A B$, the points M , N begin to move at the same time, namely, M towards A with a motion uniformly retarded, and N from rest towards B with a motion uniformly accelerated; and if the velocity of M decreases as much as the velocity of N increases in the same time; then the space $M N$ is generated by a uniform motion, equal to the velocity with which M begins to move.

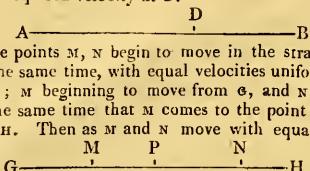

For, by hypothesis, whatever is lost in the velocity of M by retardation, is added to the velocity of N by acceleration: the joint velocities therefore of M and N , must always be equal. But it is by the joint velocities of M and N that the space $M N$ is generated. Consequently $M N$ is generated by a uniform motion, which is evidently equal to the velocity with which M begins to move.

"PROPOSITION II.—If a point begins to move in the direction of a straight line, and continues to move in the same direction with a velocity uniformly accelerated; the space passed over in any given time, will be equal to half

the space passed over in the same time with the velocity with which the acceleration ends.

Let the point D begin to move from A towards B, along the straight line AB, with a motion uniformly accelerated; the space AD passed over, is equal to half the space which the point would pass over, in the same time with the acquired velocity at D.

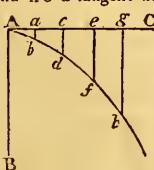

Let the points M, N begin to move in the straight line GH, at the same time, with equal velocities uniformly accelerated; M beginning to move from G, and N from H; and at the same time that M comes to the point P, let N come to H. Then as M and N move with equal veloci-

ties, uniformly accelerated, it is evident that the spaces, which they pass over in the same time, are equal to one another; consequently the space GP is equal to the space PH. Now as M begins to move from G with a velocity uniformly accelerated, it will arrive at P with an acquired velocity. Hence it is evident, if it be supposed to begin to move from P with this acquired velocity, and proceed toward G with a velocity uniformly retarded in the same degree that it was accelerated when it began to move from G, that it will pass over the same space GP in the same time. Therefore, supposing the two points M, N to begin to move from P at the same time, namely the point M beginning to move with the acquired velocity mentioned above, and proceeding towards G with the velocity uniformly retarded, described above; and the point N as before with the velocity uniformly accelerated: then, as the acceleration and retardation are uniform, they will be equal in equal spaces of time. Again; as M is retarded in the same degree that it was accelerated when it began to move from G, that is, in the same degree that N is accelerated, by the former prop., MN is generated by an uniform velocity. But when the point M arrives at G, its velocity becomes equal to 0 or nothing; and at the time that M arrives at G, N arrives at H with the acquired velocity. Therefore, as the velocities of M and N taken jointly are equal, and consequently uniform, the space GH is passed over with the velocity of N at H, in the same time that PH is passed over by N beginning to move from P with a velocity uniformly accelerated to H. But PH is half of GH. "Hence the prop. is manifest."

And hence the other laws of the spaces, before-mentioned, easily follow.

Since the spaces descended are as the squares of the times, and the abscissas of a parabola are as the squares of the ordinates, therefore the relation of the times and spaces descended may be very well represented by the ordinates and abscissas of that figure. Thus, if AB be the axis of the parabola abdfh, and AC a tangent at the vertex perpendicular to the axis, be divided into any number of equal parts aa, ac, ce, &c, to represent the times; and if there be drawn ab, cd, ef, &c, parallel to the axis: then, if ab be the space descended in the time aa, cd will be the space descended in the time ac, and ef the space descended in

the time ae, and so on continually; because, by this property of the parabola, ab, cd, ef, &c, are to each other respectively as aa², ac², ae², &c.

From the properties above demonstrated, are derived the following practical formulas or theorems. Namely, if g denote the space passed over in the first second of time, by a body urged by any constant force, denoted by 1, and t denote the time or number of seconds in which the body passes over any other space s, and v the velocity acquired at the end of that time; then, from the foregoing laws, we have $v = 2gt$, and $s = gt^2$; and from these two equations result the following general formulas:

$$s = \frac{1}{2}t^2 v = g t^2 = \frac{v^2}{4g}, \quad v = 2gt = \frac{2s}{t} = 2\sqrt{gs}.$$

$$t = \frac{v}{2g} = \frac{2s}{v} = \sqrt{\frac{s}{g}}, \quad g = \frac{v}{2t} = \frac{s}{t^2} = \frac{v^2}{4s}.$$

And when the constant force 1, is the natural force of gravity, then the distance g descended in the first second, in the latitude of London, is $16\frac{1}{2}$ feet: but if it be any other constant force, the value of g will be different, in proportion as the force is more or less.

The motion of an ascending body, or of one that is impelled upwards, is diminished or retarded by the same principle of gravity, acting in a contrary direction, after the same manner that a falling body is accelerated.

A body projected upwards, ascends until it has lost all its motion; which it does in the same time as, in falling, would have been necessary for it to have acquired that velocity. And consequently the heights to which bodies ascend, when projected upwards with different velocities, are to each other as the squares of those velocities.

It should be observed that in what has been said respecting the ascent and descent of bodies, the resistance of the atmosphere has not been considered, and therefore, in practice, the results will not accurately agree with the above theory. And further, that we have considered the force of gravity as being constant at all heights, which is not strictly true, as it varies inversely as the square of the distance from the earth's centre, (see ATTRACTION). But as the greatest height, to which we can ascend, is very small when compared with the radius of the earth, this assumption may not commonly produce any sensible error.

ACCELERATED Motion of Bodies on Inclined Planes. The same general laws obtain here, as in bodies falling freely, or perpendicularly; namely, that the velocities are as the times, and the spaces descended down the planes as the squares of the times, or of the velocities. But those velocities are less, according to the sine of the plane's inclination; and the spaces less, according to the square of the sine. See INCLINED Plane.

ACCELERATED Motion of Pendulums. See PENDULUM.

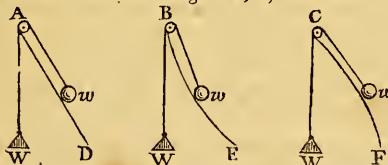

ACCELERATED Motion of Projectiles. See PROJECTILE.

ACCELERATED Motion of Compressed Bodies, in expanding or restoring themselves. See DILATATION, COMPRESSION, and ELASTICITY.

ACCELERATING FORCE, in Physics, is the force that accelerates the motion or velocity of bodies; and it is equal to, or expressed by, the quotient arising from the motive or absolute force, divided by the mass or weight of the body that is moved. In treating of physical subjects respecting forces, where velocities, times, and spaces are considered, the first inquiry is the accelerating or accelerating force. This force is greater or less in pro-

portion to the velocity it generates in the same time, and by this velocity it is measured. All accelerating forces that have the motive forces directly proportional to the quantities of matter are equal, and generate equal velocities; so a double motive force will move a double quantity of matter, with the same velocity, a triple motive force a triple quantity, a quadruple force a quadruple quantity, &c. And this is the reason why all bodies fall equally swift by the force of gravity; for the motive force is exactly proportional to their weight or mass. In general the accelerating force is in the direct ratio of the motive force, and inverse ratio of the quantity of matter. When a body is left freely to descend by the force of its natural gravity, it has been found by experiment that in the latitude of London, it falls through $16\frac{1}{2}$ feet in the first second of time, and acquires a velocity of $32\frac{1}{2}$ feet in that time: but if the quantity of matter be doubled, and the motive force remain the same as before, which may be done by connecting the falling body to another of equal weight by means of a thread, the latter body being placed on a smooth horizontal plane, along which it may be drawn without friction by the former body, which hangs freely over the side of the plane; then the accelerating force will be only half of what it was before, and the space fallen through in one second will be only $8\frac{1}{4}$ feet, and the velocity acquired $16\frac{1}{2}$: also, if the quantity of matter be tripled, or the body drawn along the plane doubled; then the accelerating force will be only one-third of what it was at first, and the space descended in one second, and the velocity acquired, will be each one-third of the first: and so on.

But accelerating forces are sometimes variable, and sometimes constant; and the variation may be either increasing or decreasing. The nature of constant and variable accelerating forces, may be illustrated in the following manner. Let two weights w , w , be connected by a

thread passing over a pulley, at A , B , or C ; and let the weight w descend perpendicularly down, while it draws the smaller weight w up the line AD , or BE , or CF , the first being a straight inclined plane, and the other two curves, the one convex and the other concave to the perpendicular. Then the small weight w will always make some certain resistance to the free descent of the large weight w , and that resistance will be constantly the same in every part of the plane AD , the difficulty to draw it up being the same in every point of it, because every part of it has the same inclination to the horizon, or to the perpendicular; and consequently the accessions to the velocity of the descending weight w , will be always equal in equal times; that is, in this case w descends by a uniformly accelerating force. But in the two curves BE , CF , the resistance or opposition of the small weight w will be constantly varying, as it is drawn up the curves, because every part of them has a different inclination to the horizon, or to the perpendicular. In the former curve, the direction becomes more and more upright, or

nearer perpendicular, as the small weight w ascends, and the opposition it makes to the descent of w necessarily becomes greater; and consequently the accessions to the velocity of w will be always less and less in equal times; that is, w descends by a decreasing accelerating force. But in the latter curve CF , as w ascends, the direction of the curve becomes less and less upright, and the opposition it makes to the descent of w , becomes always less and less; consequently the accessions to the velocity of w will be always more and more in equal times; that is, w descends by an increasing accelerating force. So that though the velocity continually increases in all these cases, yet while it increases in a constant ratio to the times of motion, in the plane AD ; the velocity increases in a less ratio than the time it ascended up BE , and in a greater ratio than the time increases in the other curve CF .

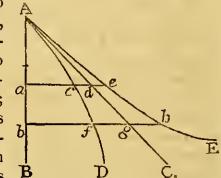

Now the relations between the times and velocities in all these cases, may be very well represented by the relations between the abscissas and ordinates of certain lines. Thus let AB and AC be two straight lines, making any angle BAC ; and AD , AE two curves, the former concave, and the latter convex towards AB ; divide AB into any parts a , a , b , &c, representing the times of motion; and draw the perpendiculars $acde$, $bfgh$, &c, representing the velocities. Then in the rightline AC , the ordinates ad , bg , being as the abscissas aa , ab , this represents the case of uniformly accelerated motion, in which the velocities are always as the times: but in the curve AD , the ordinates ae , bf increase in a less ratio than the abscissas aa , ab ; and therefore this represents the case of decreasing acceleration, in which the velocities increase in a less ratio than the times: and in the other curve AE , the ordinates ae , bh increase in a greater ratio than the abscissas; and therefore this represents the case of increasing acceleration, in which the velocities increase in a greater ratio than the times.

The several algebraic formulas or theorems, respecting the time, velocity, and space, for constant accelerating forces, have been delivered above, at the article *Accelerated Motion*, where the value of each is expressed in finite determinate quantities. But, in the cases of variably accelerated motions, the formulas will require the assistance of fluxions to express not those general relations themselves, but the fluxions of them; and consequently, taking the fluents of those expressions, in particular cases, the relations of time, space, velocity, &c, are obtained.

Thus, if t denote the time in motion,

v the velocity generated by any force,
 s the space passed over,

and φ the variable force at any part of the motion, or the velocity the force would generate in one second of time, if it should continue invariable, like the force of gravity, during that time; and therefore the value of this velocity $2g$, will be to $32\frac{1}{2}$ feet, as that variable force, is to the force of gravity. Then, because the force may be supposed constant during the indefinitely small time t , and that in uniform motions the spaces and velocities are proportional to the times, we from thence obtain these two general fundamental proportions,

$$v : s :: 1'' : i, \text{ or } s = i v;$$

$$2g : v :: 1'' : i, \text{ or } v = 2gi.$$

From which are derived the four following formulas, in which the value of each quantity is expressed in terms of the rest.

$$s = vi = \frac{v^2}{2g}, \quad v = 2gi = \frac{2gs}{i}.$$

$$i = \frac{s}{v} = \frac{\dot{v}}{2g}, \quad 2g = \frac{\dot{v}}{i} = \frac{v\ddot{v}}{s}.$$

And these theorems equally hold good for the destruction of motion and velocity, by means of retarding forces, as for the generation of the same by means of accelerating forces.

ACCELERATION, in Mechanics, the increase of velocity in a moving body.

ACCELERATION, Astron. The Diurnal Acceleration of the fixed stars, is the time which the stars, in one diurnal revolution, anticipate the mean diurnal revolution of the sun; which is $3^m 55^s \frac{2}{5}$ of mean time, or nearly $3^m 36^s$: that is, a star rises, or sets, or passes the meridian, about $3^m 56^s$ sooner each day. This acceleration of the stars, which is only apparent in them, arises from real retardation of the sun, owing to his apparent motion in his orbit towards the east, which is about $59' S \frac{2}{5}$ of a degree every day. So that the star which passed the meridian yesterday at the same moment with the sun, is to-day about $59' 8''$ past the meridian to the west, when the sun arrives at it; which will take him up about $3^m 56^s$ of time to pass over; and therefore the star passes by $3^m 56^s$ sooner than the sun each day, or anticipates his motion at that rate. The true quantity of this anticipation, or acceleration, is found by this proportion, $360^\circ 59' 8'' \frac{2}{5} : 59' 8'' \frac{2}{5} :: 24 \text{ hours} : 3^m 55^s \frac{2}{5}$, the fourth term of which is the acceleration.

The diurnal acceleration serves to regulate the lengths or vibration of pendulums in clocks. If I observe a fixed star set or pass behind a hill, steeple, or such like, when the clock marks for instance $8^h 10^m$; and the next day, the eye being in the same place as before, the passage be at $8^h 6^m 4^s$; I thence conclude that the clock is well regulated, or truly measures mean time.

ACCELERATION of a Planet. A planet is said to be accelerated in its motion, when its real diurnal motion exceeds its mean diurnal motion. And, on the other hand, the planet is said to be retarded in its motion, when the mean exceeds the real diurnal motion. This inequality arises from the change in the distance of the planet from the sun, which is continually varying; the planet moving always quicker in its orbit when nearer the sun, and slower when farther off.

ACCELERATION of the Moon, is a term used to express the increase of the moon's mean motion from the sun, compared with the diurnal motion of the earth; by which it appears that, from some uncertain cause, it is now a little quicker than it was formerly. Dr. Halley was led to the discovery, or suspicion, of this acceleration, by comparing the ancient eclipses observed at Babylon, &c, and those observed by Albategnius in the ninth century, with some of his own time; as may be seen in N° 218 of the Philosophical Transactions. He could not however ascertain the quantity of the acceleration, because the longitudes of Bagdad, Alexandria, and Aleppo, where the observations were made, had not been accurately determined. But since his time the longitude of Alexandria has been ascer-

tained by Chazelles; and Babylon, according to Ptolemy's account, lies $50'$ east of Alexandria. From these data, Mr. Dunthorne, vol. 46 Philos. Transactions, compared the recorded times of several ancient and modern eclipses, with the calculations of them by his own tables, and thereby verified the suspicion that had been started by Dr. Halley; for he found that the same tables gave the moon's place more backward than her true place in ancient eclipses; and more forward than her true place in later eclipses; and thence he justly inferred that her motion in ancient times was slower, and in later times quicker, than the tables give it.

Not content however with barely ascertaining the fact, he proceeded to determine, as well as the observations would allow, the quantity of the acceleration; and by means of an eclipse, of which the most authentic account remains, observed at Babylon in the year 721 before Christ, he found that the beginning of this eclipse was about an hour and three quarters sooner than the beginning by the tables; and that therefore the moon's true place preceded her place by computation, by about $50'$ of a degree at that time. Then, admitting the acceleration to be uniform, and the aggregate of it as the square of the time, it will be at the rate of about $10''$ or $9''$ by later computations, in 100 years.

M. de la Place announced to the Academy of Sciences the cause of this very interesting discovery in physical astronomy. Dr. Halley had remarked, as above-mentioned, that modern observations had given a more rapid motion to the moon than the ancient ones, and M. Lalande had inserted some proof of it in the memoirs of the Académie in 1757. The cause of this acceleration had been for a long time the discussion of geometers. The academy had proposed at three different times, in 1762, 70, and 72, a premium for the elucidation of this subject, but Euler himself could find nothing in the theory of attraction, which could explain this acceleration; and the learned began almost to conclude, that the difference between the ancient and modern observations was to be regarded as doubtful, and if was very possible that the Arabs, who formed the most substantial proof, might be mistaken; but M. Delambre, having calculated in 1783 the observations made by M. le Paute d'Agalet at the Military Academy, has found a new proof of this singular phenomenon. We were impatiently waiting for theory's giving us a satisfactory account of it, when M. Laplace, who so ingeniously explained in 1786 the secular equations of Jupiter and Saturn, succeeded so far, after several attempts, as to reduce that of the moon to the laws of universal weight. It is the diminution which exists for many centuries in the equation of the solar orbit, that is the cause of this inequality in the moon: but as the diminution, produced by the attraction of planets, will become, in the revolution of ages, a real augmentation, so what appears now to us an acceleration in the moon's motion, will likewise become a retardment, and it is nothing more than a periodical inequality. M. Laplace finds it eleven seconds for the first century, and as this increases within a little as the square of the time, so for the year 720 before our era, the nearest date for the most ancient observations that have reached us, it produces a difference that perfectly agrees with the observation. It is to M. Laplace, therefore, we owe a confirmation of the attraction of celestial bodies, which will prove as useful, as it is ingenious and learned.

Thus then the moon's mean motion appears to accelerate continually; and the accelerations appear to be in the duplicate ratio of the times. The acceleration for the end of the 17th century was about 9'; so that the whole motion of the moon during the 17th century must be increased 9", to obtain its motion during the 18th; and as much must be taken from it, or added to the computed longitude, to obtain its motion during the 16th; and the double of this must be taken from the motion during the 16th, to obtain its motion during the 15th, &c.—To explain the theory, it must be considered that the lunar period which we observe, is not that which would have obtained, had the moon been influenced by the earth alone. We should not have known that her natural period was increased, had the disturbing action of the sun remained unchanged; whereas this varies, and that in the inverse triplicate ratio of the earth's distance from the sun, and is therefore greater in our winter, when the earth is nearer to the sun. This is the source of the annual equation, by which the lunar period in January is made to exceed that in July nearly 24 minutes.¹ The angular velocity of the moon in general is diminished by $\frac{1}{15}$, and this numerical coefficient varies inversely as the cube of the earth's distance from the sun. If this ratio be expanded into a series arranged according to the sines and co-sines of the earth's mean motion, making the earth's mean distance 1, then the series will contain a term equal to $\frac{1}{15^2}$ of this velocity multiplied by $\frac{3}{2}$ of the square of the earth's excentricity. Had this excentricity remained constant, this product would also be constant, and would still be confounded with the general diminution, making a constant part of it: but it is known that the excentricity of the earth's orbit diminishes, and its diminution is the result of the universality of the Newtonian law of the planetary deflections. Though this diminution is exceedingly small, its effect on the lunar motion becomes sensible by accumulation in the course of ages. The excentricity diminishing, the diminution of the moon's angular motion must also diminish, that is, the angular motion must increase.

During the 18th century, the square of the earth's excentricity has diminished 0'0000015825, the mean distance from the sun being 1. In that time this has increased the moon's angular motion 0'00000001285. As this augmentation is gradual, we must multiply the angular motion during the century by the half of this quantity, in order to obtain its accumulated effect. This will be found to be 9' very nearly; which exceeds that deduced from a most careful comparison of the motion in the last two centuries, only by a fraction of a second! While the diminution of the square of the excentricity of earth's orbit can be supposed proportional to the time, this effect will be as the squares of the times. When this theory is compared with observations, the coincidence is wonderful indeed. The effect on the moon's motion is periodical, as the change of the solar excentricity is; and its period includes millions of years. Its effect on the moon's longitude will amount to several degrees before the secular acceleration change to a retardation. *Encyclopaedia Brit.*

By the solution of this problem, which had for a long time engaged the attention of mathematicians, M. Laplace has given the last degree of perfection to theoretical astronomy; as there is now no anomaly, or irregularity, in the motion of the heavenly bodies, that is not satisfac-

tory accounted for, on the simple Newtonian laws of gravitation.

ACCELERATIVE FORCE, &c, the same as ACCELERATING.

ACCESSIBLE, something that may be approached, or to which we can come. In Surveying, it is such a place as will admit of having a distance or length of ground measured from it; or such a height or depth as can be measured by actually applying a proper instrument to it. For the means of doing which, see ALTITUDE, LONGIMETRY, OR HEIGHTS-AND-DISTANCES.

ACCIDENTS, ACCIDENT, *Philos.*

Per ACCIDENTS is a term often used among philosophers, to denote what does not follow from the nature of a thing, but from some accidental quality of it: in this sense it stands opposed to *per se*, which denotes the nature and essence of a thing. Thus, fire is said to burn *per se*, or considered as fire, and not *per accidens*; but a piece of iron, though red-hot, only burns *per accidens*, by a quality accidental to it, and not considered as iron.

ACCIDENTAL, something that partakes of the nature of an accident; or that is indifferent, or not essential to its subject.—Thus, whiteness is accidental to marble, and sensible heat to iron.

ACCIDENTAL Colours, so called by M. Buffon, are those which depend on the affections of the eye, in contradistinction to such as belong to light itself.

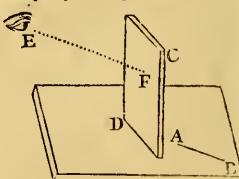

The impressions made upon the eye, by looking steadfastly on objects of a particular colour, are various according to the single colour, or assemblage of colours, in the object; and they continue for some time after the eye is withdrawn, and give a false colouring to other objects that are viewed during their continuance. M. Buffon has endeavoured to trace the connection between these accidental colours, and those that are natural, in a variety of instances. M. d'Arcy contrived a machine for measuring the duration of those impressions on the eye; and from the result of several trials he inferred, that the effect of the action of light on the eye continued about 8 thirds of a minute.

The subject has also been considered by M. de la Hire, and M. Aepinus, &c. See Mem. Acad. Paris 1743, and 1765; Nov. Com. Petrop. vol. 10; also Dr. Priestley's Hist. of Discoveries relating to Vision, pa. 631.

ACCIDENTAL Point, in Perspective, is the point in which a right line drawn from the eye, parallel to another right line, cuts the picture or perspective plane.

Let $A B$ be the line given to be put in perspective, $C F D$ the picture or perspective plane, and E the eye: draw $E F$ parallel to $A B$; so shall F be the accidental point of the line $A B$, and indeed of all lines parallel to it, since only one parallel to them, namely $E F$, can be drawn from the same point E : and in the accidental point F , there concur or meet the representations of all the parallels to $A B$, when produced.

It is called the accidental point, to distinguish it from the principal point, or point of view, where a line drawn from the eye perpendicular to the perspective plane, meets this plane, and which is the acci-

dental point to all lines that are perpendicular to the same plane.

ACCLIVITY, the slope or steepness of a line or plane inclined to the horizon, taken upwards; in contradistinction to *declivity*, which is taken downwards. So, the ascent of a hill, is an *acclivity*; the descent of the same, a *declivity*. Some writers on fortification use *acclivity* for *talus*: though more commonly the word *talus* is used to denote the slope, whether in ascending or descending.

ACCOMMODATION, in Physics, or Philosophy, the application of one thing to another by analogy.

ACCOMPANIMENT, in Music, denotes either the different parts of a piece of music for the different instruments, or the instruments themselves which accompany a voice, to sustain it, as well as to make the music more full. The Accompaniment is used in recitative, as well as in song; on the stage, as well as in the choir, &c.

The ancients had likewise their accompaniments on the theatre; and they had even different kinds of instruments to accompany the chorus, from those which accompanied the actors in the recitation. The accompaniment among the moderns, is often a different part, or melody, from the song it accompanies. But it is disputed whether it was so among the ancients. Organists sometimes apply the word to several pipes, which they occasionally touch to accompany the treble; as the drone, the flute, &c.

ACCOMP'T. See *ACCOUNT*.

ACCORD, according to the modern French music, is the union of two or more sounds heard at the same time, and forming together a regular harmony.

Accords are divided into perfect and imperfect; and again into consonances and dissonances. Accord is more commonly called **CONCORD**; which see.

ACCORD is also spoken of the state of an instrument, when its fixed sounds have among themselves all the justness that they ought to have.

ACCOUNT, or **ACCOMP'T.** in Arithmetic, &c, a calculation or computation of the number or order of certain things; as the computation of time, &c. There are various ways of accounting; as, by enumeration, or telling one by one; or by the rules of arithmetic, addition, subtraction, &c.

ACCOUNT, in Chronology, is nearly synonymous with style. Thus, we say the English, the foreign, the Julian, the Gregorian, the Old, or the New account, or style. We account time by years, months, &c; the Greeks accounted it by olympiads; the Romans, by indictions, lustræ, &c.

ACCRETION, in Physics, the growth or increase of an organical body.

ACHERNER, or **ACHARNER**, in Astronomy, a star of the first magnitude in the southern extremity of the constellation Eridanus, marked α by Bayer. Its longitude for 1761, $\aleph 11^{\circ} 55' 1''$; and latitude south $59^{\circ} 22' 4''$.

ACHILLES, a name given by the schools to the principal argument alleged by each sect of philosophers in behalf of their system. In this sense we say, this is his Achilles; that is, his master-proof: alluding to the strength and importance of the hero Achilles among the Greeks.

Zeno's argument against motion is peculiarly termed Achilles. That philosopher made a comparison between the swiftness of Achilles and the slowness of a tortoise, pretending that a very swift animal could never overtake a slow one that was before it, and that therefore there is no such thing as motion: for, said he, if the tortoise

were one mile before Achilles, and the motion of Achilles 100 times swifter than that of the tortoise, yet he would never overtake it; and for this reason, namely, that while Achilles runs over the mile, the tortoise will creep over one hundredth part of a mile, and will be so much the foremost; again, while Achilles runs over this $\frac{1}{100}$ th part, the tortoise will creep over the 100th part of that $\frac{1}{100}$ th part, and will still be this last part the foremost; and so on continually, according to an infinite series of 100th parts: from which he concluded that the swifter could never overtake the slower in any finite time, but that they must go on approaching to infinity. But this sophism lay in Zeno's considering as an infinite time, the sum of the infinite series of small times in which Achilles could run over the infinite series of spaces, $1 + \frac{1}{100} + \frac{1}{100^2} + \frac{1}{100^3} + \infty$, not knowing that the sum of this infinite series is equal to the finite small quantity $1\frac{1}{99}$ of a mile, and that therefore Achilles will overtake the tortoise when the latter has crawled over $\frac{1}{99}$ th part of a mile.

ACHROMATIC, in Optics, without colour; a term which, it seems, was first used by Dr. Bevis, to denote telescopes of a new invention, contrived to remedy aberrations and colours. See *Aberration* and *Telescope*.

ACHROMATIC TELESCOPE, a singular species of refracting telescope, said to be invented by the late Mr. John Dollond, optician to the king, and since improved by his son Mr. Peter Dollond, and others.

Every ray of light passing obliquely from a rarer into a denser medium, changes its direction towards the perpendicular; and every ray passing obliquely from a denser into a rarer medium, changes its direction from the perpendicular. This bending of the ray, caused by the change of its direction, is called its refraction; and the quality of light which subjects it to this refraction, is called its refrangibility. Every ray of light, before it is refracted, is white, though it consists of a number of component rays, each of which is of different colour. As soon as it is refracted, it is separated into its constituent rays, before mentioned, which, from that time, proceed diverging from each other, like emanations from a centre: and this divergency is caused by the different refrangibility of the component rays, in such sort, that the more the original or component ray is refracted, the more will the compounding rays diverge when the light is refracted by one given medium only. Hence it has been concluded, that any two different mediums, that can be made to produce equal refractions, will necessarily produce equal divergencies: whence it should also follow, that equal and contrary refractions should not only destroy each other, but that the divergency of the colours caused by one refraction, should be corrected by the other; and that, to produce refraction which would not be affected by the different refrangibility of light, is impossible.

But Mr. Dollond proved, by many experiments, that these conclusions are not well founded: from his experiments it appeared, that ray of light, after equal and contrary refractions, was still spread into component rays differently coloured: in other words, that two different mediums may cause equal refraction, but different divergency; and equal divergency, with different refraction. It follows therefore, that refraction may be produced, which is not affected by the different refrangibility of light; in other words, that, if the mediums be different, different refractions may be produced, though at the same time the divergency caused by one refraction, shall be

exactly counteracted by the divergency caused by the other; and so an object may be seen through mediums which, together, cause the rays to converge, without appearing of different colours.

This is the foundation of Mr. Dollond's improvement of refracting telescopes. By subsequent experiments he found, that different kinds of glass differed greatly in their refractive qualities, with respect to the divergency of colours. At the same time he found that crown glass causes the least divergency, and white flint the most, when they are wrought into forms that produce equal refractions. He therefore ground a piece of white flint glass into a wedge, the angle of which was about 25 degrees; and a piece of crown glass to another, whose angle was about 29 degrees; and these he found refracted nearly alike, but that their divergency of colours was very different.

After this, he ground several other pieces of crown glass to wedges of different angles, till he got one that was equal, in the divergency it produced, to that of a wedge of flint glass of 25 degrees; so that when they were put together, in such a manner as to refract in contrary directions, the refracted light was perfectly free from colour; then measuring the refractions of each wedge, he found that that of the white-flint glass, was to that of the crown glass, nearly as 2 to 3. And hence any two wedges, made of these two substances, and in this proportion, would, when applied together so as to refract in contrary directions, refract the light without any effect arising from the different refrangibility of the component rays.

Therefore, to make two spherical glasses that refract the light in contrary directions, one must be concave, and the other convex; and as the rays, after passing through both, must meet in a focus, the excess of the refraction must be in the convex one; and as the convex is to refract most, it appears from the experiment that it must be made of crown glass; and as the concave is to refract least, it must be made of white flint.

And farther, as the refractions of spherical glasses are in an inverse ratio of their focal distances, it follows, that the focal distances of the two glasses should be in the ratio of the refractions of the wedges: for, being thus proportioned, every ray of light that passes through this combined glass, at whatever distance it may be from its axis, will constantly be refracted by the difference between two contrary refractions, in the proportion required; and therefore the effect of the different refrangibility of light will be prevented.

The removal of this impediment, however, produced another: for the two glasses, which were thus combined, being segments of very deep spheres, the aberrations from the spherical surfaces became so considerable, as greatly to disturb the distinctness of the image. Yet, considering that the surfaces of spherical glasses admit of great variations, though the focal distance be limited; and that by these variations their aberration might be made more or less at pleasure; Mr. Dollond plainly saw that it was possible to make the aberrating of any two glasses equal; and that, as in this case the refractions of the two glasses were contrary to each other, and their aberrations being equal, these would destroy each other.

Thus he obtained a perfect theory of making object-glasses, to the apertures of which he could hardly perceive any limits: for if the practice could answer to the theory, they must admit of apertures of great extent, and consequently bear great magnifying powers.

The difficulties of the practice are, however, still very considerable. For first, the focal distances, as well as the particular surfaces, must be proportioned with the utmost accuracy to the densities and refracting powers of the glasses, which vary even in the same kind of glass, when made at different times. Secondly, there are four surfaces to be wrought perfectly spherical. However, Mr. Dollond could construct refracting telescopes on these principles, with such apertures and magnifying powers, under limited lengths, as greatly exceed any that were produced before, in forming the images of objects bright, distinct, and uninfected with colours about the edges, through the whole extent of a very large field or compass of view; of which he has given abundant and undeniable testimony. See TELESCOPE.

The defects which were yet unremedied in Mr. Dollond's telescopes, have called forth the exertions of other philosophers, and many contrivances have been invented. Father Boscovich, to whom every branch of optics is much indebted, has displayed much ingenuity in his attempts for this purpose. But the philosopher whose exertions have been attended with most success, and who appears to have made the most important discovery, in this branch of science, since the time of Newton, is Dr. Robert Blair, regius professor of astronomy in Edinburgh. By a judicious set of experiments, ably conducted, he has proved, that the quality of dispersing the rays in a greater degree than crown glass, is not confined to a few mediums, but is possessed by many fluids, and by some of them in a most extraordinary degree. He has shown, that though the greater refrangibility of the violet rays than of the red, when light passes from any medium into a vacuum, may be considered as a law of nature; yet, in the passage of light from one medium into another, it depends entirely on the qualities of the mediums as to which of these rays shall be the most refrangible, or whether there shall be any difference in their refrangibility. In order to correct the observation arising from difference of refrangibility among the rays of light, he instituted a set of experiments, by which he detected a very singular and important quality in the muriatic acid. In all the dispersive mediums hitherto examined, the green rays, which are the mean refrangible in crown glass, were found among the less refrangible; but in the muriatic acid, he found that these same rays made a part of the more refrangible.

This discovery led to complete success in removing the great defect in optical instruments, viz, that dissipation or aberration of the rays which arises from their unequal refrangibility, and has hitherto rendered it impossible to converge all of them to one point, either by single or opposite refractions. A fluid, in which the particles of marine and metalline particles hold a due proportion, at the same time that it separates the extreme rays of the spectrum much more than crown glass, refracts all the orders of the rays in the same proportion that glass does: and hence rays of all colours, made to diverge by the refraction of the glass, may either be rendered parallel, by a subsequent refraction made in the confine of the glass and this fluid; or, by weakening the refractive density of the fluid, the refraction which takes place in the confine of it and glass, may be rendered as regular as reflection, without any the least colour whatever. The doctor, it seems, has a telescope, not above 15 inches in length, with a compound object-glass of this kind, which equals in all

respects, if it does not surpass, the best of Dollond's 42 inches long. Of this object-glass, a figure may be seen in the 3d volume of the Transactions of the Royal Society of Edinburgh; to which volume the reader must be referred for a full and clear account of the experiments which led to this discovery, as well as of the important purposes to which it may be applied. A judicious abridgment of this paper may also be seen in Nicholson's Journal, vol. i, 4to, p. 1.

In the Gentleman's Magazine (1790, p. 890) a paper was published on the refracting telescope, by a person who signs *Veritas*, in which the invention is ascribed to another person, not heretofore mentioned, in these words: "As the invention has been claimed by M. Euler, M. Klingensierma, and some other foreigners, we ought, for the honour of England, to assert our right, and give the merit of the discovery to whom it is due; and therefore, without farther preface, I shall observe, that the inventor was Chester More Hall, Esq. of More-hall, in Essex, who, about 1729, as appears by his papers, considering the different humours of the eye, imagined they were placed so as to correct the different refrangibility of light. He then conceived, that if he could find substances having such properties as he supposed these humours might possess, he should be enabled to construct an object-glass that would show objects colourless. After many experiments, he had the good fortune to find those properties in two different kinds of glass; and making them disperse the rays of light in different directions, he succeeded. About 1733 he completed several achromatic object-glasses, though he did not give them this name, that bore an aperture of more than 24 inches, though the focal length did not exceed 20 inches; one of which is now in the possession of the Rev. Mr. Smith, of Charlotte Street, Rathbone Place. This glass has been examined by several gentlemen of eminence and scientific abilities, and found to possess the properties of the present achromatic glasses.

"Mr. Hall used to employ the working opticians to grind his lenses; at the same time he furnished them with the radii of the surfaces, not only to correct the different refrangibility of rays, but also the aberration arising from the spherical figure of the lenses. Old Mr. Bass, who at that time lived in Bridewell precinct, was one of these working opticians, from whom Mr. Hall's invention seems to have been obtained.

"In the trial at Westminster-hall about the patent for making achromatic telescopes, Mr. Hall was allowed to be the inventor; but Lord Mansfield observed, that 'It was not the person that locked up his invention in his scrutoire that ought to profit by a patent for such an invention, but he who brought it forth for the benefit of the public.' This, perhaps, might be said with some degree of justice, as Mr. Hall was a gentleman of property, and did not look to any pecuniary advantage from his discovery; and consequently it is very probable that he might not have an intention to make it generally known at that time.

"That Mr. Ayscough, optician on Ludgate Hill, was in possession of one of Mr. Hall's achromatic telescopes in 1754, is a fact which at this time will not be disputed"

ACHRONICAL, or *Achronyal*. See *ACRONYCHAL*.

ACIDS. All those substances which impress the organs of taste with a sharp, sour, and cooling sensation,

Vol. I.

are commonly denominated acids. But as there are some bodies destitute of this property, which are nevertheless classed by all chemical writers as acids, this popular characteristic must be abandoned as essential, for one that is more comprehensive.

The characteristic properties of acids may be enumerated as follows:

1. When taken into the mouth they occasion a sour taste.

2. They change certain vegetable blue colours to red; such as tincture of litmus, or syrup of violets; and restore the blue colours which have turned green, or the red colours which have been turned blue, by an alkali.

3. They have a stronger affinity for alkalies, than they have for any other substance.

4. They unite with earths, with alkalies, and metallic oxyds, forming the numerous and very important classes of neutral, earthy, and metallic salts.

As this article is entirely chemical, it does not accord with our plan to extend it to any considerable length; we shall therefore content ourselves with giving the most approved arrangement of acids, referring the reader, for further information on this important subject, to Thomson's Chemistry. See also Aikin's and Nicholson's Chemical Dictionaries, Encycloped. Method., Lavoisier's Elements de Chimie, Priestley on Air, Fourcroy Systeme de Connexions Chimiq. &c. &c.

ACOUSTICS, the doctrine or theory of hearing, and of sound.

Sturmians, in his Elements of Universal Mechanics, treating of Acoustics, after examining into the nature of sounds, describes the several parts of the external and internal ear, and their several uses and connexions with each other; and from thence deduces the mechanism of hearing: and lastly, he treats of the means of adding an intensity of force to the voice and other sounds; and explains the nature of echoes, of acoustic tubes, and speaking-trumpets. See SOUND, EAR, VOICE, and ECHO.

Dr. Hook, in the preface to his Micrography, asserts that the lowest whisper, by certain means, may be heard at the distance of a furlong; and that he knew a way by which it is easy to hear any one speak through a wall of three feet thick; also that by means of an extended wire,

sound may be conveyed to a very great distance, almost in an instant.

The ancients seem to have considered sounds under no other point of view than that of music; that is to say, as affecting the ear in an agreeable manner. It is even very doubtful whether they were acquainted with any thing more than melody, and whether they had any art similar to what we call composition. The moderns, by studying the philosophy of sounds, so much neglected by the ancients, have given birth to a new science distinguished by the name of acoustics, which has for its object the nature of sounds, and treats also of the theory of hearing, and the best means of assisting that sense. This science is divided by some writers into diacoustics, which explain the properties of those sounds that come directly from the sonorous body to the ear; and cata-acoustics, which treats of reflected sounds; but such distinction does not appear to be of any real utility.

On many particulars connected with this science opinions are still much divided; and a sufficient number of experiments have not been made to determine what is essential to the nature of a vehicle of sound; how it is transmitted, reflected, or destroyed, in many instances; or whether its velocity be uniform or variable.

Thus, with respect to these vehicles; as a bell or other sonorous body when struck in *vacuo* transmits no sound, it therefore necessarily follows that air is such a vehicle, or that some subtle fluid is contained in its composition which performs the office of transmitting sound: this last seems the more probable, because we know, that air is not the only vehicle, nor the best, for this transmission; and on this supposition it follows, that bodies of any density or texture will transmit sound more or less perfect, according to the quantity of this fluid contained in them.

The aqueducts constructing at Paris have lately given M. Biot an opportunity of making some interesting experiments on the propagation of sound through solid bodies, being on a larger scale than any hitherto attempted. The total length of the pipes was 3118 feet. A blow with a hammer at one extremity was heard at the other, producing two distinct sounds, the interval of which, measured in more than 200 trials, was 2 $\frac{1}{2}$ "'. And according to the experiments of the academy, the time of propagation of sound to this distance through the air should be 2 $\frac{7}{9}$ ", from which deducting 2 $\frac{1}{2}$ " the interval observed, we have 29" for the time that sound was in being propagated through the solid substance to the distance above stated. These experiments were afterwards varied; the result however generally agreed with that above stated.

Some have considered the electrical fluid as the agent by which this office is performed; it has however been objected to by others, and many ingenious arguments have been advanced on both sides, but without coming to a satisfactory conclusion. One thing however is certain, that whatever the fluid may be, the sound we hear is produced by the stroke that the sounding body makes against it, and is thence conveyed to the organ of hearing. But the manner in which this conveyance is made is still disputed: whether the sound be diffused into air in circle beyond circle, like the waves of water when we disturb the smoothness of its surface by dropping in a stone, or whether it travels along, like rays diffused from a centre, somewhat in the swift manner that electricity runs along a rod of iron, are questions which have greatly divided the opinions of the learned.

Newton was of the former opinion; but John Bernoulli confessed, that he did not understand this part of the Principia—and attempted to give a more perspicuous demonstration of his own, that might confirm and illustrate the Newtonian theory; but the subject seemed to reject elucidation; for his theory is obviously wrong, as D'Alembert has proved in his treatise on fluids.

The Newtonian theory has however found an able advocate in the ingenious Dr. Young, of Trinity College, Dublin, who has given a clear, explanatory, and able defence of the 47th proposition of the 2d book of the Principia, which has been considered the most objectionable; and some late experiments have contributed in a great degree to remove the difficulties with which this subject is clouded, and which will be explained in their proper places. See the articles CHORD, ECHO, ELASTIC STRING, EAR, SOUND, TRANSMISSION, VELOCITY, VIBRATION, &c.

ACRE, is a measure of land, containing, by the ordinance for measuring land, made in the 33d and 34th of Edward I., 160 perches or square poles of land; and as the statute length of a pole is 5 $\frac{1}{2}$ yards, or 16 $\frac{1}{2}$ feet, therefore the acre will contain 4840 square yards, or 43560 square feet. The chain with which land is commonly measured, and which was invented by Gunter, is 4 poles or 22 yards in length; and therefore the acre is just 10 square chains. Further, as a mile contains 1760 yards, or 80 chains in length, therefore the square mile contains 640 acres.

The acre, in surveying, is divided into 4 rods, and the rood is 40 perches.

The French acre, *arpent*, is equal to 1 $\frac{1}{4}$ English acre; The Strasburg contains about $\frac{1}{2}$ an English acre; The Welch acre contains about 2 English acres; The Irish acre contains 1 ac. 2 r. 19 $\frac{7}{21}$ p. English. The Scotch acre is near 1 $\frac{1}{4}$ English, being equal to 615 square yards.

Sir William Petty, in his Political Arithmetic, reckons that England contains 39 million acres: but Dr. Greve shows, in the Philos. Trans. No. 330, that England contains not less than 46 million acres. Whence he infers that England is above 46 times as large as the province of Holland, which it is said contains but about one million of acres.

By a statute of the 31st of Elizabeth, it is ordained, that if any man erect a cottage, he shall annex four acres of land to it. But this statute was repealed by the 15th of Geo. III. cap. 32.

ACROATICS, a name given to Aristotle's lectures in the more difficult and nice parts of philosophy; to which none but his disciples and intimate friends were admitted; whereas the exoteric were public or open to all.

ACRONYCHAL, or ACRONYCAL, in Astronomy, is said of a star or planet, when it is opposite to the sun. It is from the Greek *ἀργονυχός*, the point or extremity of night, because the star rose at sun-set, or the beginning of night, and set at sun-rise, or the end of night; and so it shone all the night.

The acronychal is one of the three Greek poetic risings and settings of the stars; and stands distinguished from Cosmical and Heliacal. And by means of which, from want of accurate instruments, and other observations, they might regulate the length of their year.

ACROTERIA, or ACROTERIS, in Architecture, small pedestals, usually without bases, placed on pediments, and serving to support statues. Those at the extremities

ought to be half the height of the tympanum ; and that in the middle, according to Vitruvius, one eighth part more.

ACROTERIA also are sometimes used to signify figures, whether of stone or metal, placed as ornaments or crowns, on the tops of temples, or other buildings.

It is also sometimes used to denote those sharp pinnacles or spiry battlements, that stand in ranges about flat buildings, with rails and balusters.

ACTION, in Mechanics or Physics, a term used to denote, sometimes the effort which a body or power exerts against another body or power, and sometimes it denotes the effects resulting from such effort.

Action is either instantaneous or continued ; that is, either by collision or percussion, or by pressure. These two sorts of action are heterogeneous quantities, and are not comparable, the smallest action by percussion exceeding the greatest action of pressure, as the smallest surface exceeds the longest line, or as the smallest solid exceeds the largest surface : thus, a man by a small blow with a hammer, will drive a wedge below the greatest ship on the stocks, or under any other weight ; that is, the smallest percussion overcomes the pressure of the greatest weight. These actions then cannot be measured the one by the other, but each must have a measure of its own kind, like as solids must be measured by solids, and surfaces by surfaces : time being concerned in the one, but not in the other.

It is one of the laws of nature, that action and reaction are always equal, and contrary to each other in their directions. Therefore, if a body be urged at the same time by equal and contrary forces, it will remain at rest. But if one of these forces be greater than its opposite one, motion will ensue towards the part which is least urged.

The actions of bodies on each other, in a space that is carried uniformly forward, are the same as if the space were at rest ; and any powers or forces that act upon bodies, so as to produce equal velocities in them in the same, or in parallel right lines, have no effect on their mutual actions, or relative motions. Thus the motion of bodies on board of a ship that is carried uniformly forward, are performed in the same manner as if the ship were at rest. And the motion of the earth about its axis has no effect on the actions of bodies and agents at its surface, except so far as it is not uniform and rectilineal. In general, the actions of bodies upon each other, depend not on their absolute, but relative motion.

Duality of Action, in Mechanics, a name given by Maupertuis, in the Memoirs of the Academy of Sciences of Paris for 1744, and in those of Berlin for 1746, to the continual product of the mass of a body, by the space which it runs through, and by its celerity. He lays it down as a general law, that in the changes made in the state of a body, the quantity of action necessary to produce such change is the least possible. This principle he applies to the investigation of the laws of refraction, and even to what he calls the laws of rest, that is, of the equilibrium or equipollency of pressures ; and even to the modes of acting of the Supreme Being. In this way Maupertuis attempts to connect the metaphysics of final causes with the fundamental truths of mechanics ; to show the dependence of the collision of both elastic and hard bodies, upon one and the same law, which before had always been referred to separate laws ; and to reduce the laws of motion, and those of equilibrium, to one and the same principle.

But this quantity of motion, or of action, of Maupertuis, which is defined to be the product of the mass, the space passed over, and the celerity, comes to the same thing as the mass multiplied by the square of the velocity, when the space passed over is equal to that by which the velocity is measured ; and so the quantity of force will be proportional to the mass multiplied by the square of the velocity ; since the space is measured by the velocity continued for a certain time.

In the same year that Maupertuis communicated the idea of his principle, Euler, in the supplement to his book, intitled *Methodus inveniendi lineas curvas maximi vel minimi proprietate gaudentes*, demonstrates, that in the trajectories which bodies describe by central forces, the velocity multiplied by what the foreign mathematicians call the element of the curve, always makes a minimum : which Maupertuis considered as an application of his principle to the motion of the planets.

It appears from Maupertuis's Memoir of 1744, that it was his reflections on the laws of refractions, that led him to the theorem above mentioned. The principle which Fermat, and after him Leibnitz, made use of, in accounting for the laws of refraction, is sufficiently known. Those mathematicians asserted, that a particle of light, in its passage from one point to another, through two mediums, in each of which it moves with a different velocity, must do it in the shortest time possible ; and from this principle they have demonstrated geometrically, that the particle cannot go from the one point to the other in a right line ; but being arrived at the surface that separates the two mediums, it must alter its direction in such a manner, that the sine of its incidence shall be to the sine of its refraction, as its velocity in the first medium is to its velocity in the second : whence they deduced the well known law of the constant ratio of those sines.

This explanation, though very ingenious, is liable to this pressing difficulty, namely, that the particle must approach towards the perpendicular, in that medium where its velocity is the least, and which consequently resists it the most : which seems contrary to all the mechanical explanations of the refraction of bodies, that have hitherto been advanced, and of the refraction of light in particular.

Sir Isaac Newton's manner of accounting for it, is the most satisfactory of any that has hitherto been offered, and gives a clear reason for the constant ratio of the sines, by ascribing the refraction to the attractive force of the mediums ; from which it follows, that the densest mediums, whose attraction is the strongest, should cause the ray to approach the perpendicular ; a fact confirmed by experiment. But the attraction of the medium could not cause the ray to approach towards the perpendicular, without increasing its velocity ; as may easily be demonstrated. Thus then, according to Newton, the refraction must be towards the perpendicular, when the velocity is increased : contrary to the law of Fermat and Leibnitz.

Maupertuis has attempted to reconcile Newton's explanation with metaphysical principles. Instead of supposing, with Fermat and Leibnitz, that a particle of light proceeds from one point to another in the shortest time possible ; he contends that a particle of light passes from one point to another in such a manner, that the quantity of action shall be the least possible. This quantity of action, says he, is a real expense, in which nature is always frugal. In virtue of this philosophical principle he

discovers, that not only the sines are in a constant ratio, but also that they are in the inverse ratio of the velocities, according to Newton's explanation, and not in the direct ratio, as had been asserted by Fermat and Leibnitz.

Now according to this principle, the time, that is, the space divided by the velocity, should be a minimum; so that calling the space run through in the first medium s , with the velocity v , and the space run through in the second medium s' , with the velocity v' , we shall have

Now it is easy to perceive, that the sines of incidence and refraction are to each other, as s to $-s$; whence it follows, that those sines are in the direct ratio of the velocities v, v ; which is exactly what Fermat makes it. But in order to have those sines in the inverse ratio of the velocities, it is only supposing $vs + v's = 0$; which gives $sv + sv' or s \times v + s' \times v'$ a minimum: which is Mau-pertuis's principle.

In the Memoirs of the Academy of Berlin, above cited, may be seen all the other applications which Maupertuis has made of this principle. And however unfounded his metaphysical basis of it may be, as also the idea he has annexed to the quantity of action, it will still hold good, that the product of the space by the velocity is a minimum in some of the most general laws of nature.

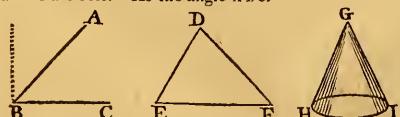

ACTIVE, the quality of an agent for communicating motion or action to some body. In this sense the word stands opposed to passive: thus we say an active cause, active principle, &c.—Sir Isaac Newton shows, that the quantity of motion in the world must be always decreasing, in consequence of the *vis inertiae*, &c. So that there is a necessity for certain active principles to recruit it: such he takes the cause of gravity to be, and the cause of fermentation; adding, that we see but little motion in the universe, except what is owing to these active principles.

ACTIVITY, the virtue or faculty of acting. As the activity of an acid, a poison, &c: the activity of fire exceeds all imagination.—According to Sir Isaac Newton, bodies derive their activity from the principle of attraction.

Sphere of Activity, is the space which surrounds a body, as far as its efficacy or virtue extends to produce any sensible effect. Thus we say, the sphere of activity of a loadstone, of an electric body, &c.

ACUBENE, in Astronomy, the Arabic name of a star of the fourth magnitude, in the southern claw of Cancer, marked α by Bayer. Its longitude for 1761, Ω $10^{\circ} 18' 9''$, south latitude $5^{\circ} 5' 56''$.

ACUTE, or sharp; a term opposed to obtuse. Thus, **ACUTE**, *Angle*, in Geometry, is that which is less than a right angle; and is measured by less than 90° , or a quadrant of a circle. As the angle $A B C$.

B C E F H I
ACUTE angle Triangle, is that whose three angles are all acute; and is otherwise called an oxygenous triangle. As the triangle DEF.

ACUTE-angled Cone, is that whose opposite sides make

an acute angle at the vertex, or whose axis, in a right cone, makes less than half a right angle with the side. As the cone GHI .

Pappus, in his Mathematical Collections, says, this name was given to such a cone by Euclid and the ancients, before the time of Apollonius. And they called an

Acute-angled Section of a Cone, an Ellipsis, which was made by a plane cutting both sides of an acute-angled cone; it being not known that such a section could be generated from any cone whatever, till it was shown by Apollonius.

ACUTE, in Music, is understood of a tone, or sound, which is high, sharp, or shrill, with regard to some other: in which sense the word stands opposed to grave. And both these sounds are independent of loudness or force: so that the tone may be acute or high, without being loud; and loud without being high or acute. For both the affections of acute and grave, depend entirely on the quickness or slowness of the vibrations by which they are produced.—Sounds considered as grave and acute, that is, in the relation of gravity and acuteness, constitute what is called tune, the foundation of all harmony.

ADAGIO, in Music, one of the terms used by the Italians to express a degree or distinction of time.

Agio denotes the slowest time except *grave*.

Sometimes the word is repeated, as *adagio*, *adagio*, to denote a still slower time than the former.

Adagio also signifies a slow movement, when used substantively.

ADAR, in the Hebrew Chronology, is the 6th month of their civil year, but the 12th of their ecclesiastical year. It contains only 29 days; and it answers to our February; but sometimes entering into the month of March, according to the course of the moon.

ADDITION, the uniting or joining of two or more quantities together.

ADDITION, in Arithmetic, is the first of the four fundamental rules or operations of that science; and, consists in finding a number equal to several others taken together, or in finding the most simple expression of, a number according to the established mode of notation; and the quantity so found is named their sum.

The sign or character of addition is +, and is called *plus*. This character is set between the quantities to be added, to denote their sum: thus, $3 + 6 = 9$; that is, 3 plus 6 are equal to 9.

Simple numbers are either added, as above; or else by placing them under one another, as in the margin, and adding them together, one after another, beginning at the bottom: thus 2 and 4 make 6, and 6 make 12.

Numbers consisting of several figures are added, by first ranging the numbers in columns under each other, placing always the numbers of the same denomination under each other, that is, units under units, tens under tens, and so on; and then adding up each column separately, beginning at the right hand, setting down the sum of each column below it, unless it amount to ten or some number of tens, and in that case setting down only the overplus, and carrying one for each ten to the next column. Thus, to add 451 and 326,

$$\text{Sum } \begin{array}{r} 451 \\ 326 \\ \hline 777 \end{array} = \begin{array}{r} 400 + 50 + 1 \\ 300 + 20 + 6 \\ \hline 700 + 70 + 7 \end{array}$$

Also to add the numbers 329 + 1562 + 20347 + 712048; set them down as in the margin, and beginning at the lowest number on the right hand, say 8 and 7 make 15, and 2 make 17, and 9 make 26; set down 6, and carry 2 to the next column, saying 2 and 4 make 6, and 4 make 10, and 6 make 16, and 2 make 18; set down 8, and carry 1, saying 1 and 3 make 4, and 5 make 9, and 3 make 12; set down 2, and carry 1, saying 1 and 2 make 3, and 1 make 4, which set down; then 1 and 2 make 3; and 7 is 7 to set down: so the sum of all together is 734286. Or it is the same as the sums of the columns set under one another, as in the margin, and then these added up in the same manner.

When a great number of separate sums or numbers are to be added, as in long accounts, it is easier to break or separate them into two or more parcels, which are added up severally; and then their sums added together for the total sum. And thus also the truth of the addition may be proved, by dividing the numbers into parcels different ways, as the totals must be the same in both cases when the operation is right.

Another method of proving addition was given by Dr. Wallis, in his Arithmetic, as well as by Lucas de Burgo, and probably by former authors, also, by casting out the nines, which method of proof extends also to the other rules of arithmetic. The method is this; add the figures of each line of numbers together, severally, casting out always 9 from the sums as they arise, in so adding, carrying the overplus to the next figure, and setting at the end of each line what is over the nine orines; then do the same by the sum-total, as also by the former excesses of 9, so shall the last excesses be equal when the work is right. Thus, the former example will be proved as annexed:

When the numbers are of different denominations; as pounds, shillings, and pence; or yards, feet, and inches; place the numbers of the same kind under each other, as pence, under pence, shillings under shillings, &c; then add each column separately, and carry the overplus as before, from one column to another. As in the following examples :

l.	s.	d.	Yards.	Feet.	Inches.
271	12	3	271	10	3
94	14	7	36	2	7
42	5	10	14	2	5
408	12	8	sums	323	0 3

ADDITION of Vulgar Fractions, is performed by bringing all the proposed fractions to the same denominator, when necessary, and all compound fractions and mixed numbers to simple fractions; then reduce all the fractions to a common denominator, and the sum of the numerators placed over the common denominator will be the answer sought.

$$\text{So } \frac{2}{3} + \frac{2}{3} = \frac{4}{3}. \quad \text{And } \frac{1}{2} + \frac{2}{3} + \frac{3}{5} = \frac{6}{5} = 1\frac{1}{5}.$$

$$\text{And } \frac{1}{2} + \frac{2}{3} + \frac{3}{4} = \frac{3}{2} + \frac{4}{3} + \frac{3}{4} = \frac{15}{4} = 3\frac{3}{4}.$$

And $\frac{5}{6} + \frac{2}{3} + \frac{3}{4} = \frac{5}{6} + \frac{4}{3} + \frac{3}{4} = \frac{4}{3} = 1\frac{1}{3}$. When the fractions are of different denominations, some further operations are necessary; thus,

$$\text{Add. } \frac{2}{3} g + \frac{3}{4} l + \frac{5}{6} s \text{ together.}$$

$$\text{Here } \frac{2}{3} g = \frac{2}{3} \times \frac{2}{3} = \frac{4}{9} s$$

329	$\frac{2}{3} l = \frac{2}{3} \times \frac{2}{3} = \frac{4}{9} s$	A D D
1562	$\frac{5}{6} s = \frac{5}{6} s$	
20347	and $\frac{4}{9} + \frac{4}{9} + \frac{5}{6} = \frac{176}{180} + \frac{180}{180} + \frac{175}{180} = \frac{371}{180} s =$	
712048	17s. 9d. $\frac{3}{4} \frac{3}{4} Ans.$	

734286	$\frac{2}{3} l = \frac{2}{3} \times \frac{2}{3} = \frac{4}{9} s$	A D D
26	the numbers of the same denomination	371·0496

ADDITION of Circulating Decimals is performed by changing each of them into its equivalent vulgar fraction, and finding the sum of such fractions.—For the method of changing, recurring or circulating decimals to vulgar fractions, see *Circulating Decimals*.

ADDITION in Algebra, is the uniting or incorporating of indeterminate quantities denoted by letters into one contracted expression. The operation is performed by connecting the quantities together with their proper signs, and collecting all similar quantities into one sum; namely, by adding their co-efficients together if their signs are the same, but subtracting them when different. Thus, the quantity a added to the quantity b , makes $a + b$; and a added to $-b$, gives $a - b$; also the compound quantity $(5a - b)$ added to $(4a + 3b)$ produces the sum $(9a + 2b)$. See the following examples :

$5xy$	$6x^2y^2$	7ab
$4ax$	$-4x^2y$	$4a^2b^2$
$-xy$	$-2axy$	$-3ab$
$-4ax$	$-3x^2y$	$-2a^2b^2$
$4xy$	$6x^2y^2 - 7xy^2 - 2axy$	$4ab + 2a^2b^2$
$2ax$	$150 + 2x^{\frac{1}{2}}$	$4y^2 - 7xy^2 + x^2$
$3x^2 + 2ax + 6x^{\frac{1}{2}}$	$4y^2 + 4xy - x^2$	
$5xy + 50 - 3x^{\frac{1}{2}}$	$3y^2 + 3xy^2 - ax^2$	
$-5x^2 + 100 + x^{\frac{1}{2}}$	$3y^3 - 2ay^2 + ax^2$	
$4ax^2 + 4x^2 + 5xy$	$7y^3 + 7y^2 - 2ay^2$	

ADDITION of Algebraic Fractions, is performed by the same rule, as has been given for addition of vulgar fractions; as will be seen by the following examples :

$$\text{Ex. } 1. \frac{x-4}{x+4} + \frac{x+3}{x+5} = \frac{7x-28}{21} + \frac{3x+9}{21} = \frac{10x-19}{21} Ans.$$

$$\text{Ex. 2. } y + \frac{3y-2a}{4} + 7y - \frac{4y-3a}{6} = 8y + \frac{y}{12} Ans.$$

ADDITION of Surds. In this rule all the given quantities must be reduced to the same denomination, or to the same radical, if that can be done; then adding or uniting the rational parts, and subjoining the common surd. Otherwise connecting them with their own signs.

So $\sqrt{8} + \sqrt{18} = \sqrt{(4 \times 2)} + \sqrt{(9 \times 2)} = 2\sqrt{2} + 3\sqrt{2} = 5\sqrt{2} = \sqrt{50}$; and $\sqrt{12} + \sqrt{27} = \sqrt{(4 \times 3)} + \sqrt{(9 \times 3)} = 2\sqrt{3} + 3\sqrt{3} = 5\sqrt{3} = \sqrt{75}$; and $\sqrt{50} + \sqrt{75} = \sqrt{(25 \times 2)} + \sqrt{(25 \times 3)} = 5\sqrt{2} + 5\sqrt{3} = (\sqrt{2} + \sqrt{3})5$; but of $\sqrt{5}$ and $\sqrt{6}$ the sum is set down $\sqrt{5} + \sqrt{6}$, because the terms are incommensurable, and not reducible to a common surd.

ADDITION of Logarithms. See Logarithms.

ADDITION of Ratios, the same as composition of ratios; which see.

ADDITIVE, denotes something to be added to another, in contradistinction to something to be taken away or

subtracted. So astronomers speak of additive equations, and geometricians of additive ratios.

ADELARD, or ATHELARD, was a learned monk of Bath, in England, who flourished about the year 1130, as appears by some manuscripts of his in Corpus Christi, and Trinity Colleges, Oxford. Vossius says he was universally learned in all the sciences of his time; and that, to acquire all sorts of knowledge, he travelled into France, Germany, Italy, Spain, Egypt, and Arabia. He wrote many books himself, and translated others from different languages: thus he translated, from Arabic into Latin, Euclid's Elements, at a time before any Greek copies had been discovered; also Erichiafarim, on the seven planets. He wrote a book on the seven liberal arts, another on the astrolabe, another on the causes of natural compositions, besides several on physics and on medicine.

Though Vossius refers to Oxford for some of these manuscripts, it would yet seem they were not to be found there in Wallis's time; for the Doctor, speaking of this author, and other English authors and travellers about the same age, says, "A particular account of these travels of Shelley and Morley was a while since to be seen in two prefaces or two manuscript books of theirs in the library of Corpus-Christi College in Oxford, but hath lately (by some unknown hand) been cut out, and carried away; which prefaces (one or both of them) did also make mention of the travels of Athelardus Bathoniensis, and are, to that purpose, cited by Vossius out of that manuscript copy. Whoever hath them, would do a kindness (by some way or other) to restore them, or at least a copy of them." Wallis's Algebra, pa. 6.

ADELM, ALDELMUS, or ATHELMLUS, a learned Englishman, who flourished about the year 680. He was first abbot of Malmesbury, and afterward bishop of Shirburn. He died in the year 709, in the monastery of Malmesbury.—Adelm was the son of Kenred or Kenten, who was the brother of Ina, king of the West Saxons in England. Besides certain books on theology, he composed several on the mathematical sciences, &c; as Arithmetic, and Astrology, and librum de philosophorum disciplinis. See Bede's History, lib. 5. cap. 19. He is also mentioned by Bale and William of Malmesbury.

ADERAIMIN, or ALDERAIMIN, the Arabic name of a star of the third magnitude, in the left shoulder of Cæsar, marked α by Bayer. Its longitude for 1761, T $9^{\circ} 30' 8''$, north latitude $65^{\circ} 56' 20''$.

ADFECTED, see AFFECTED.

ADHESION, ADHERENCE, in Physics and Chemistry, a species of attraction which takes place between the surfaces of bodies, that are either similar or dissimilar, and which in a certain degree connects them together; thus, water adheres to the fingers, mercury to gold, two pieces of lead or brass to each other, &c. Hence arises an important distinction between two words, that in a loose and popular sense are often confounded, that is, *Adhesion* and *Cohesion*.—The former denotes an union to a certain point between two similar or dissimilar substances; and the latter, that which retains together the component particles of the same mass.

The proximate cause of adhesion, has been variously stated by different philosophers. James Bernoulli attributed it to the pressure of the air; but this was afterwards found to be incorrect by some experiments made by Mr. Hauksbee; and it has since been proved, that the power of adhesion is proportional to the number of touching

points, and this depends on the figure of the particles of which the body is formed; and in solid bodies on the degree in which their surfaces are polished and compressed. Dr. Brook Taylor first observed, in 1713, the ascent of water between two planes of glass; this led him to make several experiments on the adhesive power of surfaces; from which he concluded that the degree of this force might be measured by the weight required to separate them. This idea was taken up and pursued with considerable success by M. de Morveau (now M. Guyton).

He procured cylinders, or rather plates, of different metals in their highest state of purity, which were made perfectly circular, highly polished, and furnished with a small ring fixed to their centre, each plate being exactly an inch in diameter. Those plates were in turn suspended to the arm of an assay balance, and being exactly counterpoised by weights placed in the scale attached to the opposite arm, were applied to mercury in a vessel about $\frac{1}{2}$ of an inch below them. After sliding them along the surface to prevent any air from lodging between them and the mercury, weights were successively added to the scale attached to the opposite arm, till the adhesion between the plate and the mercury was broken: and fresh mercury was used for each experiment. The results of which are exhibited in the following table.

Gold adheres to mercury with a force of	446 grains.
Silver	429
Tin	418
Lead	397
Bismuth	372
Zinc	204
Copper	142
Antimony (regulus)	126
Iron.....	115
Cobalt	8

These experiments clearly proved, as indeed had been before done by Hauksbee, that the atmosphere was not the agent or cause of adhesion; for had this been the case, it is evident that, the surfaces being the same in each experiment, the force of adhesion in each must have been equal also. The above method has been since pursued to greater lengths, and with more accuracy by M. Achard and others, who took into their account the temperature of the fluids. And from the result of these interesting experiments we may conclude—That there exists a tendency to adhesion between many, and probably between all substances in nature, absolutely independent of atmospherical or any other external pressure; that the force of this adhesion between solids is in the order of their chemical affinities; and between solids and fluids in an inverse ratio to the thermometrical temperature, and in a direct ratio to the squares of the surfaces; also that every solid adheres with a peculiar force to each fluid; that this force is truly expressed by the weight necessary to break the adhesion, in all cases where the solid comes out clear from the fluid; but that when any particles of the fluid adhere to the solid, the weight of the counterpoise is then expressive of the mixed force of adhesion between the surface of the solid and the fluid, and of the cohesion between the component particles of the latter.

In order to keep a connected view of this subject in its progress towards perfection, such experiments only have been related as most materially tended to the accomplishment of that desirable end; and consequently many cu-

rious and entertaining experiments have not been mentioned. As, however, some of these may afford a degree of satisfaction and amusement to the reader, we have detailed a few of the most interesting ones, as they are related by Musschenbroek and Martin. The former, in his Philosophy, as translated by Colson, relates that two cylinders of glass, whose diameters were not quite two inches, being heated to the degree of boiling water, and joined together by means of melted tallow lightly put between them, adhered with a force of 130 pounds: lead of the same diameter, and in similar circumstances, adhered with a force of 275 pounds, and soft iron with a force of 300 pounds. And Martin, in his Philosophia Britannica, vol. 1, says, that with two leaden balls, not weighing above a pound each, nor touching on more than $\frac{1}{10}$ of a square inch of surface, he has lifted more than 130 pounds weight: the balls being first very finely planed with the edge of a sharp pen-knife, and then equally pressed together with a considerable force, and a gentle turn of the hand. The force of adhesion between two brass plates, of about $4\frac{1}{2}$ inches diameter, and smeared with grease or fat, is so powerful, as to require more than the strength of two strong men to separate them. Those who wish to see more on this subject, may consult to advantage the Supplement to Encyclopedia Britannica, art. Chemistry, and Rees' Cyclopedia, art. Adhesion; as also the two works above mentioned.

ADHIL, in Astronomy, a star, of the 6th magnitude, on the garment of Andromeda, under the last star in her foot.

ADJACENT, whatever lies immediately by the side of another.

ADJACENT Angle, in Geometry, is said of an angle when it is immediately contiguous to another, so that they have both one common side. And the term is more particularly used when the two angles have not only one common side, but also when the other two sides form one continued right line.

ADJACENT Bodies, in Physics, are understood of those that are near, or next to, some other body.

ADJUTAGE, or rather AJUTAGE; which see.

ADSCRIPTS, in Trigonometry, is used by some mathematicians, for the tangents of arcs. Vieta calls them also prosines.

ADVANCE-FOSSE, in Fortification, a ditch thrown round the esplanade or glacis of a place, to prevent its being surprised by the besiegers.—The ditch sometimes made in that part of the lines or retrenchments nearest the enemy, to prevent him from attacking them, is also called the advance-fosse.—The advance-fosse should always be full of water, otherwise it will serve to cover the enemy from the fire of the place, if he should become master of it. Beyond the advance-fosse it is usual to construct lunettes, redouts, &c.

ADVENT, *Adventus*, in the Calendar, the time immediately preceding Christmas; and was anciently employed in pious preparation for the *adventus*, or coming on, of the feast of the Nativity.

Advent includes four Sundays, or weeks; commencing either with the Sunday which falls on St. Andrew's day, namely the 30th day of November, or the nearest Sunday to that day, either before or after.

ÆOLIPILE, *Æolipila*, in Hydraulics, a hollow ball of metal, with a very small hole or opening; chiefly used to show the convertibility of water into elastic steam. The

best way of fitting up this instrument, is with a very slender neck or pipe, to screw on and off, for the convenience of introducing the water into the inside; for, by unscrewing the pipe, and immersing the ball in water, it readily fills, the hole being pretty large; and then the pipe is screwed on. But if the pipe do not unscrew, its orifice is too small to force its way in against the included air; and therefore to expel most of the air, the ball is heated red-hot, and suddenly plunged with its orifice into water, which will then rush in till the ball is about two-thirds filled with it. The water having been introduced, the ball is set upon the fire, which gradually heats the contained water, and converts it into elastic steam, this rushes out by the pipe with great violence and noise; and thus continues till all the water is so discharged; though not with a constant and uniform blast, but by sudden ones: and the stronger the fire is, the more elastic will the steam be, and the greater the force of the blast. Care should be taken that the ball be not set upon a violent fire with very little water in it, and that the small pipe be not stopped with any thing; for in such case, the included elastic steam will suddenly burst the ball with a very dangerous explosion.

This instrument was known to the ancients, being mentioned by Vitruvius, lib. 1, cap. 6. It is also treated of, or mentioned, by several modern authors; as Descartes, in his Metcor. cap. 4; and Father Mersenne, in prop. 29 Phædron. Pneumat. uses it to weigh the air, by first weighing the instrument when red-hot, and having no water in it; and afterwards weighing the same when it becomes cold. But the conclusion gained by this means, cannot be quite accurate, as there is supposed to be no air in the ball when it is red-hot; whereas it is shown by Varenius, in his Geography, cap. 19, sect. 6, prop. 10, that the air is rarefied but about 70 times; and consequently the weight obtained by the above process, will be about one-70th too small, or more or less according to the intensity of the heat.

Descartes, and others, have made use of this instrument, to account for the natural cause and production of the wind. And hence its name, *Æolipila*, q. d. *pila Æoli*, *Æolus' ball*.

In Italy it is said that the *Æolipile* is often used to cure smoaky chimneys: for, being hung over the fire, the blast arising from it carries up the loitering smoke along with it.

And some have imagined that the *æolipile* might be employed as bellows to blow up a fire, having the blast from the pipe directed into the fire; but experience would soon convince them of their mistake; for it would rather blow the fire *out* than *up*, as it is not air, but rarefied water, that is thus violently blown through the pipe.

ÆOLUS, in Mechanics, a small portable machine, invented by Mr. Tidd, for refreshing and changing the air in rooms which are made too close. The machine is adapted to supply the place of a square of glass in a sash-window, where it works with little or no noise, on the principle of the sails of a mill, or a smoke-jack; and thus admitting an agreeable quantity of air, at a convenient part of the room.

ÆOLUS'S Harp, or *Æolian Harp*, an instrument so named, from its producing an agreeable melody, merely by the action of the wind. Neither the inventor, nor the date of the invention, of this instrument is accurately known. Kircher, in his *Magia Phonotactica* and *Phonuri-*

gia, has given the first description of it; and hence the invention of it has by some authors been attributed to him.

Its construction is extremely simple, as it consists of little more than a number of cat-gut or wire strings, distended in parallel lines over a box of thin deal, having a top of the same thin wood, with sounding-holes. Then the strings being tuned in unison, and the instrument placed in a proper situation for receiving a current of air, as an open window, &c, it produces by the tremulous motion which the wind communicates to the strings, a soft murmuring, and pleasing combination of sounds.

The late Rev. W. Jones, constructed an Æolian harp on an improved plan; the strings of which, instead of being on the outside, are fixed to a sounding-board within the box, and the wind is admitted to them through an horizontal aperture. In this form the instrument is portable and may be used in the open air. Several attempts to explain the principles of the wild harmony of this instrument have been made by different authors: of these Dr. Young's is considered as the most satisfactory, which is here subjoined. The particles of a current of air, which strike against the middle point of a stretched elastic string, will move the whole string from its rectilineal position; and as no breeze continues of the same strength for any considerable time; although it be sufficient to remove the string from its rectilineal position, yet, unless it be very rapid and violent, it will not be able to keep it bent; and consequently a vibration will ensue, and pulses in the air will be excited, which will produce the tone of the entire string. But if the current of air be too strong and rapid, when the string is bent from the rectilineal position it will not be able to recover that position, but will continue bent, like the cordage of a ship in a brisk gale. However, though the whole string cannot perform its vibrations, the subordinate aliquot parts may, which will be of different lengths in different cases according to the rapidity of the breeze. Thus, when the velocity of the current of air increases so as to prevent the vibration of the whole string, those particles which strike against the middle points of the halves of the string agitate those halves; and as these vibrate in half the time that the whole string does, notwithstanding the breeze may be too rapid to admit of the vibration of the whole string, yet it can have no more effect in preventing the motion of the halves, than it would have on the whole were its tension quadruple; for the times of vibrations of strings of different lengths, agreeing in other circumstances, are directly as the lengths; and in strings of different tensions, and agreeing in other circumstances, inversely as the square roots of the tensions (see CHORD): and therefore, their vibrations may become strong enough to excite such pulses as will affect the drum of the ear: and the same may be said of the other aliquot divisions of the string. Those particles which strike against such points of the string as are not in the middle or aliquot parts, will interrupt and counteract each other's vibration, as is the case of sympathetic and secondary tones, and therefore will not produce a sensible effect. When Æolian notes are heard, which are not produced by any submultiples of the string, they are very transitory, and immediately vary their pitch, till they coincide with the notes the next above or below them, which are produced by the exact aliquot parts of the whole string: and thus the harmony is never interrupted by long-continued discords.

ÆRA, in Chronology, is the same as epoch, or epocha, and means a fixed point of time, from which to begin a computation of the years ensuing. The word is sometimes also written era in ancient authors. Its origin is contested, though it is commonly supposed that it had its rise in Spain, others say from the Arabs. Some imagine that it is formed from *a. er. a.* the abbreviations of the words, *annus erat Augusti*, or from *a. e. r. a.* the initials of the words *annus erat regni Augusti*, because the Spaniards began their computation from the time that their country came under the dominion of Augustus. Others derive it from *as*, brass, the tribute money with which Augustus taxed the world. It is also said that *era* originally signified a number stamped on money to determine its current value; and that the ancients used *as* or *ara* as an article, as we do the word *item*, to each particular of an account; and hence it came to stand for a sum or number itself.

ÆRA also means the way or mode of accounting time. Thus we say, such a year of the Christian æra, &c.

Spanish ÆRA, otherwise called the year of Cæsar, was introduced after the second division of the Roman provinces, between Augustus, Anthony, and Lepidus, in the 714th year of Rome, the 4676th year of the Julian period, and the 38th year before Christ. In the 447th year of this æra, the Alani, the Vandals, Suevi, &c, entered Spain. It is frequently mentioned in the Spanish affairs; their councils, and other public acts, being all dated according to it. Some say it was abolished under Peter IV, king of Aragon, in the year of Christ 1358, and the Christian æra introduced instead of it. But Mariana observes that it ceased in the year of Christ 1383, under John I, king of Castile. The like was afterwards done in Portugal.

Christian ÆRA. It is generally allowed by Chronologists, that the computation of time from the birth of Christ, was only introduced in the sixth century in the reign of Justinian; and it is commonly ascribed to Dionysius Exiguus. This æra came then into use in deeds, &c; before which time, either the olympiads, or the year of Rome, or that of the reign of the emperors, was used for such purposes.

See an account of the other principal æras under the word Epoch.

AERIAL Perspective, is that which represents bodies diminished and weakened, in proportion to their distance from the eye.

Aerial Perspective chiefly relates to the colours of objects, whose force and lustre it diminishes more or less, to make them appear as if more or less remote. It is founded upon this, that the longer the column of air an object is seen through, the more feebly do the visual rays emitted from it affect the eye.

AEROGRAPHY; a description of the air, or atmosphere, its limits, dimensions, properties, &c.

AEROLITHS, or AEROLITES, i. e. Air-stones, or stones from the atmosphere, are those compound kind of masses which sometimes fall from the atmosphere, in all countries, and which are therefore often called meteoric stones.—The descent of any such bodies was for a long time doubted, the popular opinion that attested the reality being mostly regarded as a vulgar prejudice; but the fact has been often proved of late, in such a manner as to leave no reasonable doubt of the existence of the phenomenon. See an account of many of these descents,

described in my paper on this subject, in the Abridg. Philos. Trans. vol. 6, pa. 100, as well as several other accounts there referred to.

The following table, drawn up by M. Izaron, a philosopher who has paid considerable attention to the history

<i>Substances fallen.</i>	<i>Places where they fell.</i>	<i>Times of their fall.</i>	<i>Testimonies.</i>
Shower of sulphur	Sodom and Gomorrah	Year before J. C. 1898.....	Moses
Shower of stones	At Rome	Under Tullius Hostilius	Livy
Shower of stones	At Rome	Consuls C. Martius & M. Torquatus.....	J. Obsequens
Shower of iron	In Lucania	Year bef. defeat of Crassus	Pliny
Shower of Mercury	In Italy	Dion
A very large stone	Near the river Negos, Thrace	2d year of 78th Olympiad	Pliny
Three large stones	In Thrace	Year before J. C. 452.....	Ch. of Count Marcellin
Mass of iron, 14 quintals	Abakaick, Siberia	Very old	Pallas, Chladni, &c
Large stone, 260lbs	Ensisheim, Upper Rhine	Nov. 7th, 1492.....	Butenschoen
About 1200 stones; one 120lbs. another of 60lbs.	Near Padua, in Italy	In 1510.....	Cardin, Varait
Another, of 59lbs.	Mount Vaiser, Provence	Nov. 27, 1627	Gassendi
Sulphurous rain	Copenhagen	In 1646.....	Olaus Wormius
The same.....	Duchy of Mansfeld	In 1658.....	Spaenburg
Shower of viscid matter	Iceland	In 1695.....	Muschenbroeck
Stone of 72lbs	Macedonia	January 1706	Paul Lucas
Shower of fire	Quesnoy	Jan. 4th, 1717	Groffroy le Cadet
Shower of sand for 15 hours	Atlantic Ocean	April 6, 1719	Pere le Feuillé
Shower of sulphur	Brunswick	October 1721	Siegesber
A stony mass	Niort, Normandy	In 1750	Lafande
Shower of stones	Near Tabor, Bohemia	July 3d, 1753	B. de Born
Two stones, wt. 20lbs	Liponas in Bresse	September 1753	Lalande
Two do. 200 and 300lbs	Near Verona	In 1762	Acad. de Bourd
A stone of 7½lbs	At Luce, in Le Maine	Sept. 13, 1768	Bachelay
A stone	Aire, in Artois	In 1768	Gurson de Boyaval
A stone	In Le Cotentin	In 1768	Morand
Shower of stones	Near Roquefort	July 1789	Darct, jun. Lomet, &c
Extensive do.	Environs of Agen	July 24, 1790	St. Amand, Baudin, &c
About 12 stone	Sienna, Tuscany	July 1794	Earl of Bristol
Large stone of 56lbs	Wold-Cottage, Yorks.	Dec. 13, 1795	Capt. Topham
A stone of 10lbs	In Portugal	Feb. 19, 1796	Southey
A stone of 20lbs	Sales, near Ville-Franche..	March 12, 1798	De Drée
A stone of 20lbs	Sale, dept. of the Rhône ..	March 17, 1798	Lefèvre & De Drée
Shower of stones	Benares, East Indies	Dec. 19, 1798	J. Lloyd Williams
Mass of iron, 70 cubic ft....	America	April 5, 1800	Philos. Magazine
Some stones, from 10 to 17lbs	L'Aigle, Normandy	April 20, 1803	Fourcroy

To this list might be added many more instances, and among them several of more recent date. Of these masses, the larger kinds have been seen as luminous bodies moving with very great velocities, descending in oblique directions, commonly with a loud hissing noise, resembling that of a mortar shell, or cannon ball, or rather that of an irregular hard mass, violently projected through the air; surrounded by a blaze or flame, tapering off to a narrow stream in the hinder part; they are heard to explode or burst, and even to fly in pieces, the larger parts going foremost, and the smaller following in succession: they are thus seen to fall on the earth, striking it with great violence; and, on examining the place of the fall, the parts are found scattered about, being still considerably warm, and mostly entered several inches deep in the earth. But their most remarkable character is, that they have a perfect resemblance to one another. They are always found to be different from the neighbouring bodies, and show in every case the same appearance of semimetallic matter, coated on the outside with a thin black incrustation, and bearing strong marks of re-

cent fusion. Besides, several of these singular substances have been very carefully examined and analysed by Fourcroy, Howard, Bournois, Lavoisier, Vauquelin, and other eminent chemists and naturalists in Europe; and it has been found that all the substances examined agree very nearly in nature and composition, having the same component materials, and in nearly the same proportions: thus, the stones examined by Count de Bournon and Mr. Howard, were found to consist of four distinct substances, a peculiar martial pyrites, a number of globular and elliptical bodies, also of a peculiar nature, and an earthy cement surrounding the other component parts. The nature of the metallic particles was the same in all, being in each an alloy of iron and nikel. In the pyrites, nikel as well as iron was detected; and the easy decomposition of the pyrites, by muriatic acid, afforded a distinguishing character of that substance. The globules contained magnesia, silica, with oxides of nikel and iron. The earthy cement consisted of the same substances nearly in the same proportions. With regard to the proportions of these constituents, the celebrated stone which fell at En-

sisheim, in Alsace, in 1492, and those which fell at l'Aigle, in France, in 1803, were found to yield, by the analyses of Fourcroy and Vauquelin, the proportions following, viz, at

Ensisheim.	L'Aigle.
56·0..... of silica.....	54
30·0..... oxyd of iron.....	36
12·0..... magnesia	9
2·4..... nikel	3
3·5..... sulphur.....	2
1·4..... lime	1
105·3	105

It likewise appears that the specific gravities of these bodies are nearly alike, and such as greatly to exceed all the known ordinary stones, and approach that of the metallic ores. Thus, the specific gravity of

the Ensisheim stone was	3233
Benares.....	3352
Sienna.....	3418
Gassendi's	3456
Yorkshire	3508
Bachelay's.....	3535

of such parts as that of water is 1000.

These common and constant characters indicate, with strong evidence, a common origin. Yet, it is to be remarked, that iron is hardly ever found in the metallic state in terrestrial bodies: volcanic bodies only containing it in the state of oxyd. Nikel is also very rare, being never found on the surface of the earth. Whence it appears natural to conclude, that aerolites have an origin foreign to our globe, or at least that they are not produced by phenomena that have been commonly observed. Various hypotheses have therefore been devised to account for the origin of these stones. Some philosophers think that they are nothing else than small planets, that circulate in space after the manner of the other celestial bodies; and which, when found engaged in the earth's atmosphere, become there inflamed, by the resistance and friction they experience; that they lose little by little their velocity, and at length fall to the earth by their gravitation. Mr. King, Sir Wm. Hamilton, and others, consider these stones as concretions actually formed in the atmosphere; while others have imagined such phenomena as resulting from electricity. But, in my Abridg. of the Philos. Trans. (vol 6, p. 100), I have shown not only that it is possible, but even highly probable, that they may have been projected on the earth by lunar volcanoes. On subjecting this idea to calculation, it has been found that a projectile force only the triple of that sometimes given to cannon balls, would be sufficient to carry a body out of the sphere of the moon's influence, so that the terrestrial gravitation would draw it towards our planet. Nor is it at all improbable, that lunar volcanoes might impress such a force on a body, since terrestrial volcanoes can communicate a much greater impulsion. This opinion acquires a fresh degree of probability from the recent observations of M. Schroeter on the moon, with respect to the great height of some of the lunar volcanoes, and the frequent variations observed on the surface of that globe. Thus, then, the probability of this origin of the aerolites appears to be greatly in favour of this last opinion; though, in the present state of our knowledge of these substances and of meteorology, it is not possible as yet to decide. For accounts of the phenomena of many aerolites, the inquisitive reader may

consult Mr. Howard's valuable paper in the Philos. Trans. for the year 1802, as well as my dissertation above referred to.

AERONOLOGY, the doctrine or science of the air, and its phenomena, its properties, good and bad qualities, &c. It is much the same with the foregoing word, Aerography.

AEROMETRY, *Aerometria*, the science of measuring the air, its powers and properties; comprehending not only the quantity of the air itself, as a fluid body, but also its pressure or weight, its elasticity, rarefaction, condensation, &c.

The term is not much used at present; this branch of natural philosophy being usually called pneumatics, which see. Wolfius, late professor of mathematics at Hall, having reduced several properties of the air to geometrical demonstrations, first published at Leipzig his Elements of Aerometry, in the German language, and afterwards more enlarged in Latin, which have since been inserted in his Cursus Mathematicus, in five volumes in 4to.

AERONAUTICA, the pretended art of sailing through the air, or atmosphere, in a vessel, sustained as a ship in the sea.

AEROSTATICA, is properly the doctrine of the weight, pressure, and balance of the air and atmosphere.

AEROSTATION, in its proper and primary sense, denotes the science of weights suspended in the air; but in the modern application of the term, it signifies the art of navigating or floating in the air, both as to the practice and principles of it. Hence also the machines which are employed for this purpose, are called aerostats, or aerostatic machines; and which, on account of their form, are otherwise called air-balloons. Also aeronaut is the name given to the person who navigates or floats in the air by means of such machines.

Principles of AEROSTATION. The fundamental principles of this art have been long and generally known, as well as speculations on the theory of it; but the successful application of them to practice seems to be altogether a modern discovery. These principles chiefly respect the weight or pressure, and elasticity of the air, with its specific gravity, and that of the other bodies to be raised or floated in it: the particular detail of which principles may be seen under the respective words in this dictionary. Suffice it therefore in this place to observe, that any body which is specifically lighter than the atmosphere, will be buoyed up by it, and ascend, as wood, or a cork, or a blown bladder, ascends in water. And thus the body would continue to ascend to the top of the atmosphere, if it were every where of the same density as at the surface of the earth. But as the air is compressible and elastic, its density decreases continually in ascending, on account of the diminished pressure of the superincumbent air, at the higher elevations above the earth; and therefore the body will ascend only to that height where the air is of the same specific gravity with itself; there the body will float, and move along with the wind or current of air which it may meet with at that place. This body then is an aerostatic machine, of whatever form or nature it may be. And an air-balloon is a body of this kind, the whole mass of which, including its covering and contents, and the weights annexed to it, is of less weight than the same bulk of air in which it rises.

We know of no solid bodies however that are light enough thus to ascend and float in the atmosphere; and

therefore recourse must be had to some fluid or aeriform substance.

Among these, that which is called hydrogen gas, or inflammable air, is the most proper of any that has hitherto been discovered. It is very elastic, and from 6 to 10 or 12 times lighter than common atmospheric air at the surface of the earth, according to the different methods of preparing it. If therefore a sufficient quantity of this gas be inclosed in a very thin bag or covering, the weight of the two together will be less than the weight of the same bulk of common air; and consequently this compound mass will rise in the atmosphere, and continue to ascend till it attain a height at which the atmosphere is of the same specific gravity as itself; where it will remain or float with the current of air, as long as the inflammable air does not escape through the pores of its covering. And this is an inflammable-air balloon.

Another way is to make use of common air, rendered lighter by warming it, instead of the inflammable air. Heat, it is well known, rarefies and expands common air, and consequently lessens its specific gravity; and the diminution of its weight is proportional to the heat applied. If therefore the air, inclosed in any kind of a bag or covering, be heated, and consequently dilated, to such a degree, that the excess of the weight of an equal bulk of common air, above the weight of the heated air, be greater than the weight of the covering and its appendages, the whole compound mass will ascend in the atmosphere, the same as in the former case; till, by the cooling and condensation of the included air, the balloon shall gradually contract and descend again, unless the heat is renewed or kept up. And such is a heated-air or fire balloon, otherwise called a Montgolfier, from its inventor.

Now it has been discovered, by various experiments, that one degree of heat, according to the scale of Fahrenheit's thermometer, expands the air about one five-hundredth part; and therefore that it will require about 500 degrees, or nearer 484 degrees of heat, to expand the air to just double its bulk. Which is a degree of heat far above what it is practicable to give it on such occasions. And therefore, in this respect, common air heated, is much inferior to hydrogen gas.

But, before entering more particularly into this subject, it will be proper to give a short historical account of its rise and progress, with the various experiments and aerial voyages, that have been made of later years by divers aeronauts.

History of AEROSTATION. Various schemes for rising in the air, and passing through it, have been devised and attempted, both by the ancients and moderns, and that upon different principles, and with various success. Of these, some attempts have been upon mechanical principles, or by virtue of the powers of mechanism: and such are conceived to be the instances related of the flying pigeon made by Archytas, the flying eagle and fly by Regiomontanus, and various others. Again, some projects have been formed, by attaching wings to some part of the human body, which were to be moved either by the hands or feet, by the help of mechanical powers; so that, striking the air with them, after the manner of the wings of a bird, the person might raise himself in the atmosphere, and transport himself through it, in imitation of that animal. But of these, and various other devices of the like nature, a particular account will be given under the article *artificial flying*, as belonging rather to that species of

principle of motion, than to our present subject of aero-station, which is properly the sailing or floating in the air by means of a machine rendered specifically lighter than that element, in imitation of aqueous navigation, or the sailing upon the water in a ship, or vessel, which is specifically lighter than the water.

The first rational account upon record, for this kind of sailing, is perhaps that of our countryman Roger Bacon, who died in the year 1292. He not only affirms that the art is practicable, but assures us that he himself knew how to make an engine, in which a man sitting might be able to carry himself through the air like a bird; and he farther affirms, that there was another person who had tried it with success. The secret it seems consisted in having a couple of large thin shells, or hollow globes, of copper, exhausted of air; so that the whole being thus rendered lighter than air, they would support a chair, in which a person might sit.

Bishop Wilkins too, who died in 1672, in several of his works, makes mention of similar ideas being entertained by divers persons. "It is a pretty notion to this purpose," says he, (in his *Discovery of a New World*, prop. 14), mentioned by Albertus de Saxonia, and out of him by Francis Mendoza, that the air is in some part of it navigable. And that upon this statick principle, any brass or iron vessel (suppose a kettle), whose substance is much heavier than that of the water; yet being filled with the lighter air, it will swim upon it, and not sink." And again, in his *Dedalus*, chap. 6, "Scaliger conceives the framing of such volant automata to be very easy. Volantis columbae machinulam, cuius autem Archytam tradunt, vel facilime profiteri audeo. Those ancient motions were thought to be contrived by the force of some included air: So Gellius, Ita erat scilicet libramentis suspensum, et aura spiritus inclusa, atque occulta constitutum, &c. As if there had been some lamp, or other fire within it, which might produce such a forcible rarefaction, as should give a motion to the whole frame." From which it would seem that Bishop Wilkins had some confused notion of such a thing as a heated-air balloon.

Again, F. Francisco Lana, in his *Prodroma*, printed in 1670, proposes the same method with that of Roger Bacon, as his own thought. He considered that a hollow vessel, exhausted of air, would weigh less than when filled with that fluid; he also reasoned that, as the capacity of spherical vessels increases much faster than their surface, if there were two spherical vessels, of which the diameter of one is double the diameter of the other; then the capacity of the former will be equal to 8 times the capacity of the latter, but the surface of that only equal to 4 times the surface of this: and if the one sphere have its diameter equal to triple the diameter of the other, then the capacity of the greater will be equal to 27 times the capacity of the less, while its surface is only 9 times greater: and so on, the capacities increasing as the cubes of the diameters, while the surfaces increase only as the squares of the same. And from this mathematical principle, father Lana deduces, that it is possible to make a spherical vessel of any given matter, and thickness, and of such a size as, when emptied of air, it will be lighter than an equal bulk of that air, and consequently that it will ascend in that element, together with some additional weight attached to it. After stating these principles, father Lana computes that a round vessel of plate brass, 14 feet in diameter, weighing 3 ounces the square foot, will

only weigh 1848 ounces; whereas a quantity of air of the same bulk will weigh 2155 $\frac{1}{2}$ ounces, allowing only one ounce to the cubic foot; so that the globe will not only ascend in the air, but will also carry up a weight of 307 $\frac{1}{2}$ ounces: and by increasing the bulk of the globe, without increasing the thickness of the metal, he adds, a vessel might be made to carry a much greater weight.

Such then were the ingenious speculations of learned men, and the gradual approaches towards the perfection of this art. But one thing more was yet wanted: though acquainted in some degree with the weight of any quantity of air, considered as a detached substance, it seems they were not aware of its great elasticity, and the universal pressure of the atmosphere; by which pressure, a globe of the dimensions above-described, and exhausted of its air, would immediately be crushed inwards, for want of the equivalent internal counter pressure, to be sought for in some element, much lighter than common air, and yet nearly of equal pressure or elasticity with it; a property or circumstance attending inflammable gas, and also common air when considerably heated.

It is evident then, that the schemes of ingenious men hitherto must have gone no farther than mere speculation; otherwise they could never have recorded fancies, which, on the first attempt to put in practice, must have manifested their own insufficiency, by an immediate failure of success. For, instead of exhausting the vessel, it must either be filled with common air heated, or with some other equally elastic and lighter fluid. So that upon the whole it appears, that the art of traversing the air, is an invention of our own time; and the whole history of it is comprehended within a very short period:

Mr. Cavendish was the first who discovered with any degree of accuracy the specific gravity of inflammable air; and his experiments and observations upon it, are published in the 56th volume of the Philosophical Transactions for the year 1766.

Soon after this discovery of Mr. Cavendish, it occurred to the ingenious Dr. Black of Edinburgh, that if a bladder, or other vessel, sufficiently light and thin, were filled with this air, it would form altogether a mass lighter than the same bulk of atmospheric air, and consequently that it would ascend in it. This idea he mentioned in his chemical lectures in the year 1767 or 1768; and he further proposed to exhibit the experiment, by filling the allantois of a calf with such air. The allantois, however, was not prepared just at the time when he was at that part of his lectures, and other avocations afterwards prevented his design: so that, considering it only as an amusing experiment, and being fully satisfied of the truth of so evident an effect, he contented himself with barely mentioning the experiment from time to time in his lectures.

About the year 1777 or 1778 it also occurred to Mr. Cavallo, that it might be possible to construct a vessel, which, when filled with inflammable air, would ascend in the atmosphere: and there is no doubt but that similar ideas occurred to many other persons, of so evident a consequence of Mr. Cavendish's discovery. But it seems to have been Mr. Cavallo who first actually attempted the experiments, in which however he succeeded no further than in being able to raise soap bubbles of two or three inches diameter: a thing which had been done by children for their amusement from time immemorial. These experiments Mr. Cavallo made in the beginning of the year 1782, and an account of them was read at a

public meeting of the Royal Society on the 20th of June of that year. From which it appears that he tried bladders and paper of various kinds. But the bladders, however thin they were made by scraping, &c., were still found too heavy to ascend in the atmosphere, when duly inflated with the inflammable air: and in using China paper, he found that this air passed through its pores, like water through a sieve. So that, having failed of success by blowing the same air into a thick solution of gum, thick varnishes, and oil paint, he was obliged to rest satisfied with soap-balls or bubbles, which, being filled with inflammable air, by dipping the end of a small glass tube, connected with a bladder containing the air, into a thick solution of soap, and gently compressing the bladder, ascended rapidly, and broke against the ceiling of the room.

Here, however, it seems the matter might have rested, had it not been for experiments made in France soon after, by the two brothers Stephen and Joseph Montgolfier, on principles suggested, not by the levity of inflammable air, which probably they had never heard of, but by that of smoke and clouds ascending in the atmosphere. These two brothers it seems were natives of Annonay, a town in the Vivarais, about 36 miles from Lyons; and that in their youth, Stephen, the elder, had assiduously studied the mathematics, but the other had applied himself more particularly to natural philosophy and chemistry. They were not intended for any particular way of business, but the death of a brother obliged them to put themselves at the head of a considerable paper manufacture at Annonay. In the intervals of time allowed by their business they amused themselves in several philosophical pursuits, and particularly with the experiments in aerostation, of which we are now to give some account. It would be perhaps impossible to know all the particular steps and ideas which finally produced this discovery: but it has been said that the real principle, on which the effect of the aerostatic machine depends, was unknown even for a considerable time after its discovery: that Montgolfier attributed the effect of the machine, not to the rarefaction of the air, which is the true cause, but to a certain gas, specifically lighter than common air, which was supposed to be developed from burning substances, and which was commonly called Montgolfier's gas. Be this however as it may, it is well known that the two brothers began to think of the experiment of the aerostatic machine about the middle or the latter part of the year 1782. The natural ascension of the smoke and the clouds in the atmosphere, suggested the first idea; and to imitate those bodies, or to inclose a cloud in a bag, and let the latter be lifted up by the buoyancy of the former, was the first project of those gentlemen.

Accordingly, the first experiment was made at Avignon by Stephen, about the middle of November 1782. Having prepared a bag of fine silk, in the shape of a parallelopipedon, and of about 40 cubic feet in capacity, he applied burning paper to an aperture in the bottom, which rarefied the air, and thus formed a kind of cloud in the bag; and when it became sufficiently expanded, it ascended rapidly to the ceiling.

Soon afterwards the experiment was repeated with the same machine at Annonay, by the two brothers, in the open air; when the bag ascended to the height of about 70 feet. Encouraged by this success, they constructed another machine, of about 650 cubic feet capacity; which, when inflated as before, broke the cords which

confined it, and after ascending rapidly to the height of about 600 feet, descended and fell on the adjoining ground. With another larger machine, of 37 feet diameter, they repeated the experiment on the 25th of April, which answered exceedingly well: the machine had such force of ascension, that, breaking abruptly from its confinement of ropes, it rose to the height of more than 1000 feet, and then, being carried by the wind, descended and fell at a place about three quarters of a mile from the place of its ascension. The capacity of this machine was equal to above 23 thousand cubic feet, and, being nearly globular, when inflated, it measured 117 English feet in circumference. The covering was formed of linen, lined with paper; and its aperture at the bottom was fixed to a wooden frame, of about 4 feet square, or 16 feet in surface. When filled with vapour, which it was conjectured might be about half as heavy as common air, it was capable of lifting up about 490 pounds, besides its own weight, which, together with that of the wooden frame, was equal to about 500 pounds. With this machine the next experiment was publicly performed at Annony, on the 5th of June 1783, before a great multitude of spectators. The flaccid bag was suspended on a pole 35 feet high; straw and chopped wool were burned¹⁰ under the opening at the bottom; the vapour, or rather smoke, soon inflated the bag, so as to distend it in all its parts; and this enormous mass ascended in the air with such velocity, that in less than ten minutes it reached the height of above 6 thousand feet; when a breeze carried it in an horizontal direction to the distance of near a mile and a half, where it descended gently to the ground.

As soon as the news of this experiment reached Paris, the philosophers of that city, conceiving that a new species of gas, of about half the weight of common air, had been discovered by Messrs. Montgolfier; and knowing that the weight of inflammable air was but about the 8 or 10th part of the weight of common air, they justly concluded that inflammable air would answer the purpose of this experiment better than the gas of Montgolfier, and accordingly they resolved to make trial of it.

A subscription was opened by M. Faujas de St. Fond, towards defraying the expense of the experiment. A sufficient sum of money having soon been raised, Messrs. Roberts were appointed to construct the machine, and M. Charles, professor of experimental philosophy, to superintend the work. After a considerable time spent, and surmounting many difficulties in obtaining a sufficient quantity of this gas, and searching out a substance light enough for the covering, they at length constructed a globe of the silk called lustrestring, which was rendered impervious to the inclosed air by a varnish of elastic gum or caeutchouc, dissolved in some kind of spirit or essential oil. The diameter of this globe was about 13 feet; and it had only one aperture, like a bladder, to which a stop-cock was adapted: the weight of this covering, when empty, together with that of the stop cock, was 23 pounds.

On the 23d of August 1783, they began to fill the globe; but this, being their first attempt, was attended with many obstructions and disappointments, which took up two or three days to overcome. At length, however, it was prepared for exhibition, and on the 27th it was carried to the Champs de Mars, a spacious open ground in the front of the Military School, where, after introducing some more inflammable air, and disengaging it from the cords by which it was held down, it rose, in

less than two minutes, to the height of 3123 feet: the weight of the balloon, when it went up, being 35 pounds less than that of an equal bulk of common air. After floating in the air for about three quarters of an hour, it fell in a field at 15 miles from the place of its ascent; where, as we may easily imagine, it occasioned great amazement to the peasants who found it. Its fall was owing to a rent in the covering, probably occasioned by the superior elasticity of the inflammable air, over that of the rare part of the atmosphere to which it had ascended.

In consequence of this brilliant experiment, numberless small balloons were made, mostly of gold-beater's skin, from 6 and 9 to 18 or 20 inches diameter; their cheapness putting it in the power of almost every family to satisfy its curiosity relative to the new experiment; and in a few days balloons were seen flying all about Paris, whence they were soon sent abroad.

M. Joseph Montgolfier repeated an experiment with a machine of his construction before the commissioners of the Academy of Sciences, on the 11th and 12th of September. The machine was about 74 feet high, and 43 feet in diameter; it was made of canvass, covered with paper both within and without, and weighed 1000 pounds. It was filled with rarefied air in 9 minutes, and in one trial¹¹ the weight of 8 men was not sufficient to keep it down. It was not suffered to go up, as it had been intended for exhibition before the Royal Family, a few days after. By the violence of the rain, however, which fell about this time, it was so much spoiled, that he thought proper to construct another for that purpose, in which he used so great di-patch, that it was completed in the short space of four days. This machine was constructed of cloth made of linen and cotton thread, and painted with water colours both within and without. Its height was 60 feet, and diameter 43 feet. Having made the necessary preparation for inflating it, the operation was begun about one o'clock on the 19th of the same month, before the king and queen, the court, and the inhabitants of the place, as well as all the Parisians who could procure a conveyance to Versailles. The balloon was soon filled, and in 11 minutes after the commencement of the operation, the ropes being cut, it ascended, bearing up with it a wicker cage, containing a cock, a duck, and a sheep, the first animals that ever ascended into the atmosphere with an aerostatic machine. Its power of ascension, or the weight by which it was lighter than an equal bulk of common air, allowing for the animals and their cage, was 696 pounds. The balloon rose to the height of 1440 feet; and being driven by the wind for about 8 minutes, it gradually descended, in consequence of two large rents made in the covering by the wind, and fell in wood at the distance of about two miles from Versailles. The animals landed again as safe as when they went up, and the sheep was found feeding.

The success of this experiment induced M. Pilatre de Rozier, with a philosophical intrepidity which will be recorded with applause in the history of aerostation, to offer himself as the first adventurer in this aerial navigation. For this purpose, M. Montgolfier constructed a new machine, of an oval shape, in a garden of the faubourg St. Antoine; its diameter being about 48 feet, and height 74 feet. To the aperture in the lower part was annexed a wicker gallery about three feet broad, with a ballustrade of three feet high. From the middle of the aperture an

iron grate, or brazier, was suspended by chains, descending from the sides of the machine, in which a fire was lighted for inflating the machine; and towards the aperture port-holes were opened in the gallery, through which any person, who might venture to ascend, might feed the fire on the grate with fuel, and regulate at pleasure the dilatation of the air inclosed in the machine: the weight of the whole being upwards of 1600 pounds. On the 15th of October 1783, the fire being lighted, and the balloon inflated, M. P. de Rozier placed himself in the gallery, and, to the astonishment of a multitude of spectators, ascended as high as the length of the restraining cords would permit, which was about 84 feet from the ground, and there kept the machine afloat near 5 minutes, by repeatedly throwing straw and wool upon the fire: the machine then descended gradually and gently, through a medium of increasing density, to the ground; and the intrepid adventurer assured the admiring spectators that he had not experienced the least inconvenience in this aerial excursion. This experiment was repeated on the 17th with nearly the same success; and again several times on the 19th, when M. Rozier, by a partial ascent and descent, several times repeated, evinced to the multitude of observers, that the machine may be made to ascend and descend at the pleasure of the aeronaut, by merely increasing or diminishing the fire in the grate. The balloon having been hauled down, by the ropes which always confined it, M. Gironde de Villette placed himself in the gallery opposite to M. Rozier, and the machine being suffered to ascend, it hovered for about 9 minutes over Paris, in the sight of all its inhabitants, at the height of 330 feet. And on their descending, the marquis of Arlandes ascended with M. Rozier much in the same manner.

In consequence of the report of these experiments, signed by the commissioners of the Academy of Sciences, it was ordered that the annual prize of 600 livres should be given to Messrs. Montgolfier for the year 1783.

In the experiments above-recited, the machine was always secured by long ropes, to prevent its entire escape: but they were soon succeeded by unconfined aerial navigation. For this purpose, the same balloon, of 74 feet in height, was conveyed to La Muette, a royal palace in the Bois de Boulogne: and all things being ready, on the 21st of November 1783, M. Rozier and the marquis d'Arlandes took their post in opposite sides of the gallery, and at 2 o'clock the machine was abandoned to the element, when it ascended calmly and majestically in the atmosphere. On reaching the height of about 280 feet the intrepid aeronauts waved their hats to the astonished multitude: but they soon after rose too high to be distinguished, their greatest height being estimated at 3000 feet. At first they were driven, by a north-west wind, horizontally over the river Seine and part of Paris, taking care to clear the steeples and high buildings by increasing the fire; and in rising they met with a current of air which carried them southward. Having thus passed the Boulevard, and finally desisting from supplying the fire with fuel, they descended very gently in a field beyond the new Boulevard, a little more than 5 miles from the palace de La Muette, having been between 20 and 25 minutes in the air. The weight of the whole apparatus, including that of the two travellers, was between 1600 and 1700 pounds.

Notwithstanding the rapid progress of aerostation in France, it is remarkable that we have no authentic account of any experiments of this kind being attempted in

other countries. Even in our own island, where all arts and sciences find an indulgent nursery, and many their birth, no aerostatic machine was seen before the month of November 1783. Various speculations have been made on the reasons of this strange neglect of so novel and brilliant an experiment. But none seemed to carry any show of probability except that it was said to be discouraged by the leader of a philosophical society, expressly instituted for the improvement of natural knowledge, for the reason, as it was said, that it was the discovery of a neighbouring nation. Be this however as it may, it is a fact that the first aerostatic experiment was exhibited in England by a foreigner unconnected and unsupported. This was a count Zambecari, an ingenious Italian, who happened to be in London about that time. He made a balloon of oiled-silk, 10 feet in diameter, weighing only 11 pounds: it was gilt, both for ornament, and to render it more impermeable to the inflammable air with which it was to be filled. The balloon, after having been publicly shown for several days in London, was carried to the Artillery Ground, and there being about three-quarters filled with inflammable air, and having a direction inclosed in a tin box for any person by whom it should afterwards be found, it was launched about one o'clock on the 25th of November 1783. At half past 3 it was taken up near Petworth in Sussex, 48 miles distant from London; so that it travelled at the rate of near 20 miles an hour. Its descent was occasioned by a rent in the silk, the effect of the rarefaction of the inflammable air, when the balloon ascended to a rarer part of the atmosphere.

The French philosophers having executed the first aerial voyage with a balloon inflated by heated air, resolved to attempt a similar voyage with a balloon filled with inflammable air, which seemed to be preferable to dilated air in every respect, the expense of preparing it only excepted. A subscription was opened however to defray that expense, which was estimated at about ten thousand livres; and the balloon was constructed by Messrs. Roberts, of gores of silk, varnished with a solution of elastic gum. Its form was spherical, and it measured 27½ feet in diameter. The upper hemisphere was covered by a net, which was fastened to a hoop encircling its middle, and called its equator. To this equator was suspended by ropes a car or boat, covered with painted linen, and beautifully ornamented, which swung a few feet below the balloon. To prevent the bursting of the machine by the expansion of the inflammable air in a rarer medium, or to cause the balloon to descend, it was furnished with a valve, which might be opened by means of a string descending from it, for discharging a part of the internal air, without admitting the external to enter: And the car was ballasted with bags of sand, for the purpose of lightening it occasionally, and causing it to ascend: so that by letting some of the air escape through the valve, they might descend; and by discharging some of their sand ballast, ascend. To this balloon was likewise annexed a long pipe by which it was filled. The apparatus for this purpose consisted of several casks placed round a large tub of water, each having a long tin tube, that terminated under a vessel or funnel, which was inverted into the water of the tub, and communicated with the long pipe annexed to the lower part of the balloon. Iron filings and diluted vitriolic acid being put into the caskets, the inflammable air which was produced from these materials, passed through the tin tubes, thence through the

water of the tubs to the inverted funnel, and so through the pipe into the balloon. When inflated, the weight of the common air which was equal in bulk to the balloon, was $771\frac{1}{2}$ pounds; also the power of ascension, or weight just necessary to keep it from ascending, was 20 pounds, and weight of the balloon, with its car, passengers, and all its appendages, was $604\frac{1}{2}$ pounds, making in all $624\frac{1}{2}$ pounds: and this taken from $771\frac{1}{2}$ pounds, the weight of common air displaced, leaves 147 pounds for the weight of the inflammable air contained in the balloon, and which is to $771\frac{1}{2}$ pounds, the weight of the same bulk of common air, nearly as 1 to $5\frac{1}{2}$; that is, the inflammable air used in this experiment was $5\frac{1}{2}$ times lighter than common air.

The first of December was fixed on for the display of this grand experiment; and every preparation was made for conducting it with advantage. The garden of the Tuilleries at Paris was the scene of operation; which was soon crowded and encompassed with a prodigious multitude of observers. Signals were given, from time to time, by the firing of cannon, waving of flags, &c: and a small montgolfier was launched, for showing the direction of the wind, and for the amusement of the people previous to the general display.. At a quarter before 1 o'clock, M. Charles and one of the Roberts, having seated themselves in the boat attached to the balloon, and being furnished with proper instruments, cloathing, and provisions, left the ground, and ascended with a moderate velocity to the height of about 600 yards; the surrounding multitude standing silent with fear and amazement; while the aerial navigators at this height made signals of their safety. When they left the ground, the thermometer, according to Fahrenheit's scale stood at 59° ; and the barometer, at $30\cdot18$ inches: at the utmost height to which they ascended, the barometer fell to 27 inches; from which they deduced their height as above, to be 600 yards, or one third part of a mile. During the rest of the voyage the quicksilver in the barometer was generally between 27 and $27\cdot65$ inches, rising and falling, as part of the ballast was thrown out, or some of the inflammable air escaped from the balloon. The thermometer generally stood between 53 and 57 degrees. Soon after their ascent, they remained stationary for some time: they then moved horizontally in a direction N.N.W.: and having crossed the Seine, and passed over several towns and villages, to the great amazement of the inhabitants, they descended in a field, about 27 miles from Paris, at three-quarters past 3 o'clock; so that they had travelled at the rate of near 15 miles an hour, without feeling the least inconvenience.

The balloon still containing a considerable quantity of inflammable air, M. Charles re-ascended alone, and it was computed he went to the height of 3100 yards, or near 2 miles, the barometer being then at 20 English inches: having amused himself in the air about 33 minutes, he pulled the string of the valve, and descended at 3 miles distance from the place of his ascent. All the inconvenience he experienced in his great elevation, was a dry sharp cold, with a pain in one of his ears and a part of his face, which he ascribed to the dilatation of the internal air: a circumstance that usually happens to persons who suddenly change the density of their atmosphere, either by ascending into a rarer, or descending into a denser one. The small balloon, launched at the beginning by M. Montgolfier, was found to have moved in a direction

opposite to that of the aeronauts; from which it is inferred that there were two currents of air at different heights above the earth.

In the month of December this year, several experiments were made at Philadelphia in America with air-balloons, by Messrs. Rittenhouse and Hopkins. They constructed and filled a great many small balloons, and connected them together; by which a man went up several times, and was drawn down again; and finally, the ropes being cut, he ascended to the height of 100 feet, and floated to a considerable distance; but, being afraid, he cut open the balloons with a knife, and so descended.

About the close of this year small balloons were sent up in many places, and were become very common in some parts of France and England. In the beginning of the year following, their number and magnitude increased considerably. Some of the more remarkable ones were as follow:—On the 19th of January M. Joseph Montgolfier, accompanied by six other persons, ascended from Lyons with a rarefied-air balloon, to the height of 1000 yards. This was the largest machine that had been hitherto made, being 131 feet high, and 104 feet in diameter: it was formed of a double covering of linen, with three layers of paper between them; and it weighed, when it went up, 1600 pounds, including the gallery, passengers, &c. It was at first intended for six passengers; but before it went up, it was not judged safe to freight it with more than three: however, no authority nor solicitations could prevail upon any of the six to quit their place, nor even to cast lots which three should resign their pretensions: so that the spectators saw them all ascend with terror and anxiety; and to add to their distress, when the ropes were cut, and the machine had ascended a foot or two from the ground, a seventh person suddenly leaped into the gallery, and the fire being increased, the whole ascended together. To add to the terror of the scene, after being in the air about 15 minutes, a large rent of about 50 feet in length was made by the balloon taking fire, in consequence of which it descended very rapidly to the ground, though fortunately without injury to any of the aeronauts.

On the 22d of February an inflammable-air balloon was launched from Sandwich in Kent. It was but a small one, being only 5 feet in diameter; but it was rendered remarkable by being the first machine that crossed the sea from England to France. It was found in a field at Warneton, about 9 miles from Lisle in French Flanders, two hours and a half after it left Sandwich, the distance being about $7\frac{1}{4}$ miles; so that it floated at the rate of about 30 miles an hour.

The chevalier Paul Andreani, of Milan, was the first aerial traveller in Italy. The chevalier himself was at the sole expense of this machine, but was assisted in the construction by two brothers of the name of Gerli. They all three ascended together near Milan on the 25th of February, and remained in the atmosphere about 20 minutes, when they descended, all their fuel being exhausted. This machine was a montgolfier, of a spherical shape, and about 68 feet in diameter. From calculations made on the power of this, and other machines of the same sort, it appears that the included air is rarefied commonly but about one-third, or that the included warm air weighs about two thirds of the same bulk of the external or common air.

The next aerial voyage was performed on the 2d of

March 1784, by M. Jean Pierre Blanchard, a man who has since that time made more voyages than any other person, except M. Garnerin, and who has attained great celebrity by being the first who has floated in the air over the channel from England to France. M. Blanchard it seems had for many years been in pursuit of mechanical means for flying through the air; but on hearing of the late invented air-balloons, he dropped his former pursuits, and turned his attention to them. He accordingly constructed a balloon of 27 feet diameter, to which a boat was suspended, with two wings, and a rudder to steer it by, as also a large parachute spread horizontally between the boat and the balloon, designed to check the fall in case the balloon should burst. The machine being filled with inflammable air, he ascended, from the Champs de Mars at Paris, to the height of near 2 miles; and after floating in the air for an hour and a quarter, he descended at Billancourt, near Seve, having experienced by turns heat, cold, hunger, and an excessive drowsiness. It appears from his own account, and as might have been expected, that the wings and rudder of his boat had little or no power in turning the balloon from the direction of the wind.

In the course of this year, 1784, aerostatic experiments and aerial voyages became so frequent, that the limits of this article will not allow of any thing farther than mentioning those that were attended with any remarkable circumstances. On the 25th of April, Messrs. de Morveau and Bertrand ascended from Dijon, with an inflammable-air balloon, to the height of near 2 miles and a half, where the thermometer marked 25°. They were in the air an hour and 25 minutes, in which time they floated 18 miles.

On the 20th of May, four ladies and a gentleman ascended from Paris, in a large montgolfier, above the highest buildings, and remained suspended there a considerable time, the balloon being confined by ropes from flying away.

On the 23d of May, M. Blanchard, with the same balloon as before, ascended from Rouen, to such height that the mercury in the barometer stood at 20° 57 inches, which on the earth had been at 30° 16'. It was observed that in this voyage M. Blanchard's wings or oars could not turn him aside from the direction of the wind.

On the 4th of June M. Fleurant and Madame Thible, the first lady who made an aerial voyage, ascended at Lyons in a machine of 70 feet diameter. They went to the height of 8500 feet, and floated about 2 miles in 45 minutes.

On the 14th of June, M. Constant de Massi and M. Mouchet ascended at Nantes to a great height, with a balloon of 32 $\frac{1}{2}$ feet diameter, filled with inflammable air extracted from zinc; and they floated to the distance of 27 miles in 58 minutes.

On the 23d of June, the first aerial traveller M. Rozier, accompanied with M. Prouts, ascended at Versailles, in the presence of the royal family and the king of Sweden, with a large montgolfier, whose diameter was 79 feet, and its height 91 feet and a half. They floated to the distance of 36 miles in three-quarters of an hour, when they descended, which is at the rate of 48 miles an hour. In consequence of this experiment, the king granted to M. de Rozier a pension of 2000 livres.

On the 15th of July the duke of Chartres, the two brothers Roberts, and a fourth person, ascended from the park of St. Cloud, with an inflammable-air machine, of

an oblong form, its diameter being 34 feet, and its length, which went in a direction parallel to the horizon, was 55 $\frac{1}{2}$ feet: they remained in the atmosphere 45 minutes, in the greatest fear and danger. The machine contained an interior small balloon, filled with common air, by means of which it was proposed to cause the machine to ascend or descend without the loss of any inflammable air or ballast: and the boat was furnished with a helm and oars, which were intended to guide it. Three minutes after ascending, the machine was lost in the clouds, and involved in a dense vapour. A violent agitation of the air, resembling a whirlwind, greatly alarmed the aeronauts, turned the machine three times very rapidly, and gave it such shocks as prevented them from using any of their instruments for managing the machine. After many struggles, with great difficulty they tore about 7 or 8 feet of the lower part of the covering, by which the inflammable air escaped, and they descended to the ground with great rapidity, though without any hurt. At the place of departure the barometer stood at 30° 12' inches, and at their greatest elevation it descended to 24° 36'; so that their ascent was nearly a mile.

On the 18th of July, M. Blanchard, with a Mr. Boley, made his third voyage with the same balloon as he had before, and rose so high as to sink the barometer from 30° 1 to 25° 34 inches, answering to a height of about 4600 feet. In 2 hours and a quarter they floated 45 miles, which is at the rate of 20 miles an hour. In this voyage M. Blanchard thought that he was able to turn the machine with his wings, and to make it ascend and descend at pleasure. After descending, it is said the balloon remained all the night at anchor full of air; and that the next day several ladies amused themselves by ascending successively to the height of 80 feet, the length of the ropes by which it was anchored.

In the course of this summer two persons had nearly lost their lives by ascending with machines of heated air. The one in Spain, on the 5th of June, by the machine taking fire, was much burnt, and so hurt by the fall that his life was long despaired of. The latter having ascended a few feet, the machinery entangled under the eaves of a house, which broke the ropes, and the man fell about twenty feet: the machine presently took fire, and was consumed. Other montgolfiers were also burned about London, by taking fire, through the defects of their construction.

The first aerial voyage performed in England was by one Vincent Lunardi, a native of Italy, who ascended from the Artillery Ground, London, with an inflammable-air balloon on 15th of September. His machine was made of oiled silk, painted in alternate stripes of blue and red; and its diameter was 33 feet. From a net, which covered about two thirds of the balloon, 45 cords descended to a hoop hanging below it, to which the gallery was attached. The machine had no valve; and its neck, which terminated in the form of a pear, was the aperture through which the inflammable air was introduced, and through which it might be let out. The balloon was filled with air produced from zinc by means of diluted vitriolic acid. And when the aeronaut departed at 2 o'clock he took up with him a dog, a cat, and a pigeon. After throwing out some sand, to clear the houses, he ascended to a considerable height; and the direction of his motion at first was north-west by west; but as the balloon rose higher, it came into another current of air, which carried

it nearly north. In the course of his voyage the thermometer was as low as 29° , and the drops of water which had collected round the balloon were frozen. About half after 3 he descended very near the ground, and landed the cat, which was almost dead with cold : then rising, he prosecuted his voyage, till at 10 minutes past 4 o'clock he landed near Ware in Hertfordshire. He ascribes his descent to the action of his oars; but as he was under the necessity of throwing out ballast in order to re-ascend, his descent was more probably occasioned by the loss of inflammable air.

The longest and most interesting voyage performed about this time, was that of Messrs. Roberts and M. Colin Hullin, who ascended at Paris, at noon on the 19th of September, with a balloon, filled with inflammable air, which was $27\frac{3}{4}$ feet in diameter, and $46\frac{3}{4}$ feet long, the machine being made to float with its longest part parallel to the horizon, and having a boat of near 17 feet long attached to it. The boat was fitted up with several wings or oars, shaped like an umbrella; and they ascended at 12 o'clock with 450 pounds of sand ballast, and after various manoeuvres finally descended, at 40 minutes past 6 o'clock, near Arras in Artois, 150 miles from Paris, having still 200 pounds of ballast remaining in the boat. In one part they found the current of air uniform from 600 to 4200 feet high, which it seems was their greatest height, and the fall of the barometer had been near $5^{\circ}6^{\prime}$ degrees. They found that by means of their oars they could accelerate their course a little in the direction of the wind, when it moved slowly, which may be true ; but there is great reason to doubt of the accuracy of their experiments by which they pretended to cause their path to deviate about 22 degrees from the wind, going with a considerable velocity.

The second aerial voyage in England, was performed by Mr. Blanchard, and Mr. Sheldon, professor of anatomy to the Royal Academy, being the first Englishman who ascended with an aerostatic machine. They ascended at Chelsea the 16th of October, at 9 minutes past 12 o'clock. Mr. Blanchard having landed Mr. Sheldon at about 14 miles from Chelsea, re-ascended alone, and finally landed near Rumsey in Hampshire, about 75 miles from London, having gone nearly at the rate of 20 miles an hour. The wings used on this occasion it seems produced no deviation from the direction of the wind. Mr. Blanchard said that he ascended so high as to feel a great difficulty of breathing: and that a pigeon, which flew away from the boat, laboured for some time to sustain itself with its wings in the rarefied air, but after wandering a good while, returned, and rested on the side of the boat.

On the 4th of October, Mr. Sadler, an ingenious tradesman at Oxford, ascended at that place with an inflammable-air balloon, of his own construction and filling. And again on the 12th of the same month he ascended at Oxford, and floated to the distance of 14 miles in 17 minutes, which is at the rate of near 50 miles an hour.

The 30th of November this year Mr. Blanchard's fifth aerial voyage, still with his old machine, was performed in company with Dr. J. Jeffries, a native of America. Their voyage was about 21 miles; and it does not appear that the greatest action of their oars produced any effect in directing the course of the balloon.

On the 4th of January, 1785, a Mr. Harper ascended at Birmingham with an inflammable-air balloon, and went to the distance of 50 miles in an hour and a quarter : he

suffered no other inconvenience than a temporary deafness, and what might be expected from the changes of wet and cold. The thermometer descended from 40 to 28 degrees.

On the 7th of January, Mr. Blanchard, accompanied by Dr. Jeffries, performed his sixth aerial voyage, by actually crossing the British channel from Dover to Calais, with the same balloon which had five times before carried him successfully through the air. They ascended with only 30 pounds of sand ballast, besides their provisions, some books, instruments, and other necessaries. The machine parted with the gas very rapidly, and their ballast was soon all exhausted; after which, from time to time they threw out every thing else in the boat, to prevent themselves from dropping into the sea. In this way they disposed of all their provisions, their books and instruments, and finally with part of their clothes. This however bringing them near the French coast, they gradually ascended, cleared the cliffs and houses, and landed in the forest of Guinees. In consequence of this voyage, the king of France presented M. Blanchard with a gift of 12000 livres, and granted him a pension of 1200 livres a year.

On the 19th of January, Mr. Crosbie ascended at Dublin in Ireland with an inflammable-air balloon to a great height. He rose so rapidly, that he was out of sight in 3 minutes and a half. By suddenly opening the valve, he descended just at the edge of the sea, as he was driving towards the channel, being unprovided for properly passing over to England.

On the 23d of March, Count Zambeccari and Admiral Sir Edward Vernon ascended at London, and sailed to Horsham in Sussex, at the distance of 35 miles in less than an hour. The voyage proved very dangerous, owing to some of the machinery about the valve being damaged, which obliged them to cut open some part of the balloon when they were about 2 miles perpendicular height above the earth, the barometer having fallen from 30 \cdot 4 to 20 \cdot 8 inches. In descending, they passed through a dense cloud, which felt very cold, and covered them with snow. The observations they made were, that the balloon kept perpetually turning round its vertical axis, sometimes so rapidly as to make each revolution in 4 or 5 seconds; that a peculiar noise, like rustling, was heard among the clouds, and that the balloon was greatly agitated in the descent.

On May the 5th, Mr. Sadler, and William Windham, esq. member of parliament for Norwich, ascended at Moulseay-hurst. The machine took a south-east course, and the current of air was so strong, that they were in great danger of being driven to sea. They had the good fortune however to descend near the conflux of the Thames and Medway, not a mile from the water's edge. By an accident they lost their balloon: for while the aeronauts were busied in securing their instruments, the country people, whom they had employed in holding down the machine, suddenly let go the cords, when the balloon instantly ascended, and was driven many miles out to sea, where it fell, and was taken up by a trading vessel. It was afterwards restored again, and another voyage made with it from Manchester to Pontefract, in which Mr. Sadler was still more unfortunate; for no person being near when he descended, and not being able to confine the balloon by his own strength, he was dragged by it over trees and hedges; and at last was forced to quit it at the utmost peril of his life; after which it rose again,

and was out of sight in a few minutes. It was afterwards found near Gainsborough.

On the 12th of May, Mr. Crosbie ascended, at Dublin, as high as the tops of the houses; but soon descended again with a velocity that alarmed all the spectators for his safety. On his stepping out of the car, in an instant Mr. McGuire, a college youth, sprang into it, on which the balloon ascended with him to the astonishment of the beholders, and presently he was carried with great velocity towards the channel in the direction of Holyhead. This being observed, a crowd of horsemen pursued full speed the course he seemed to take, and could plainly perceive the balloon descending into the sea. Lord H. Fitzgerald, who was among the foremost, instantly dispatched a swift-sailing vessel mounted with oars, and all the boats that could be got, to the relief of the gallant youth; whom they found almost spent with swimming, just time enough to save his life.

The fate of M. Pilatre de Rozier, the first aerial traveller, and his companion M. Romain, has been much lamented. They ascended at Boulogne the 15th of June, with intent to cross the channel to England: for the first 20 minutes they seemed to take the proper direction; when presently the whole apparatus was seen in flames, and the unfortunate adventurers fell to the ground from the height of more than a thousand yards, and were killed on the spot, their bones being broken, and their bodies crushed in a shocking manner. The machine in which they ascended, consisted of a spherical balloon, 37 feet in diameter, filled with inflammable air; and under this was suspended a small montgolfier, or fire balloon, of 10 feet diameter; the gallery which suspended the aeronauts, was attached to the net of the upper balloon by cords, which were fastened to a hoop rather larger than the montgolfier, and descended perpendicularly to the gallery. The montgolfier was intended to promote and prolong the ascension, by rarefying the atmospheric air.

On the 19th of July, at 20 minutes past 2 o'clock, Mr. Crosbie a third time ascended at Dublin, with intent to cross the channel to Holyhead in England. The usual form of the boat had been changed, for a capacious wicker basket, of a circular form; and round its upper edges were fastened a great many bladders, which were intended to render his gallery buoyant, in case of a disaster at sea. About 300 pounds of ballast were put into the basket, but he discharged half a hundred on his first rise. At first a current of air carried him due west; but it soon changed his course to north-east, pointing towards Whitehaven. At upwards of 40 miles from the Irish shore, he found himself within sight of both lands, and he said it was impossible to give an adequate idea of the beauties which the scenery of the sea, bounded by both lands, presented. He rose at one time so high, that by the intense cold his ink was frozen, and the mercury sunk quite into the ball of the thermometer. He was sick, and felt a strong propulsion on the tympanum of the ears. At his utmost height he thought himself stationary; but on liberating some gas, he descended to a current of air blowing north, and extremely rough. He now entered a thick cloud, and encountered strong blasts of wind, with thunder and lightning, which brought him rapidly towards the surface of the water. Here the balloon made a circuit, but falling lower, the water entered his car, and he lost his notes of observation. All his endeavours to throw out ballast were of no avail; the force of the wind plunged

him into the ocean; and with much difficulty he put on his cork jacket. The propriety of his idea was now very manifest in the construction of his boat; as by the admission of the water into the lower part of it, and the suspension of his bladders, which were arranged at the top, the water, added to his own weight, became proper ballast; and the balloon maintaining its poise, it became a powerful sail, by means of which, and a snatch-block to his car, he went before the wind as regularly as a sailing vessel. In this situation he found himself inclined to eat, and he took a little fowl. At the distance of a league he discovered some vessels crowding after him; but as his progress outstripped all their endeavours, he lengthened the space of the balloon from the car, which gave a check to the rapidity of his sailing, and he was at length overtaken and saved by the Dunleary barge, which took him on board, and steered to Dunleary, towing the balloon after them.

A similar accident happened to Major (now General) Money, who ascended at Norwich, on the 22d of July, at 20 minutes past 4 in the afternoon; when meeting with an improper current, and not being able to let himself down, on account of the smallness of the valve, he was driven out to sea, where, after blowing about for near two hours, he dropped into the water. Here the struggles were astonishing which he made to keep the balloon up, which was torn, and hung only like an umbrella over his head. A ship was once within a mile, but, whether from want of humanity, or by mistaking the balloon for a sea monster, they sheered off, and left him to his fate; but a boat chased him for two hours, till just dark, and then bore away. He now gave up all hopes, and began to wish that Providence had given him the fate of Rozier, rather than such a lingering death. Exerting himself however to preserve life as long as possible, by keeping the balloon floating over his head, to keep himself out of the water, into which nevertheless he sunk gradually inch by inch, as it lost its power, till he was at length breast deep in water, when he was taken up by a revenue cutter, at half past eleven at night, but so weak that he was obliged to be lifted out of the car into the ship.

About the latter end of August, the longest aerial voyage hitherto made, was performed by Mr. Blanchard, who ascended at Lisle, accompanied by the Chevalier de L'Epinard, and travelled 300 miles in their balloon before it descended. On this occasion, as on some former ones, Mr. Blanchard made trial of a parachute, like a large umbrella, invented to break the fall in case of an accident happening the balloon; with this machine he dropped a dog from the car soon after his ascension, which descended gently and unhurt.

On the 8th of September, Thomas Baldwin, esq. ascended from the city of Chester, and descended at Rixton-Moss, at 23 miles' distance, after a voyage of 2 hours and a quarter. The greatest perpendicular altitude ascended was about a mile and a half, and the aeronaut computed that in some parts of the voyage he moved at the rate of 30 miles an hour. Mr. Baldwin published a very circumstantial account of his voyage, with many ingenious philosophical remarks relating to aerostation, of which subject his book may be considered as one of the best treatises yet given to the public.

October the 5th, Mr. Lunardi made the first aerial voyage in Scotland. He ascended at Edinburgh, and, after various turnings, landed near Cupar in Fife, having de-

scribed a track of 40 miles over the sea, and 10 over the land, in an hour and a half. The mercury in the barometer sunk as low as 18°3 inches at his greatest elevation.

November the 19th, the celebrated Blanchard ascended at Ghent to a great height, and after many dangers descended at Delft without his car, which he cut away to lighten the machine when he was descending too rapidly, and slung himself by the cords to the balloon, which served him then in the nature of a parachute. On his first ascent, when he was almost out of sight, he let down a dog, by means of a parachute, which came easily to the ground.

November the 25th, Mr. Lunardi ascended at Glasgow, and in two hours it is said he described a track of 125 miles. It is further remarkable that, being overcome with drowsiness, he slept for about 20 minutes in the bottom of the car, during this voyage.

In order to obviate the danger of a fall, arising from any accident happening to the balloon, some experiments were made with a parachute first by Mr. Blanchard, who performed several other excursions in different parts of Europe, and made some improvements in the parachute, wings, &c. An account of the two following voyages performed by him will be best related in Mr. Blanchard's own words, taken from his letter, dated Leipsick, October the 9th, 1787, to the editors of the Paris Journal. "I did not mention," says he, "in your interesting paper, my ascension at Strasburg on the 26th of last August: the weather was so horrible, that I mounted only for the sake of contenting the astonishing crowd of strangers, assembled there from all parts of the country. The only remarkable thing that occurred at that time, was the following circumstance: At the height of about 2000 yards, or a mile and half a quarter, I let down a dog tied to the parachute, which, instead of descending gently, was forcibly carried by a whirlwind above the clouds. I met him soon after, bending his course directly downwards: when he perceived me, he began to bark a little, and I was going to take hold of the parachute, when another whirlwind lifted him again to a great height. I lost him for about 6 minutes, and perceived him afterwards, with my telescope, as if sleeping in the cradle or basket belonging to the machine. Continually agitated, and impetuously tossed through every point of the compass, by the violence of the different currents of air, I determined to end my voyage on the other side of the Rhine, after having passed vertically over Zell. I descended at a small village, with an intention to be assisted a little, and about thirty men soon came within reach of the balloon very a-propos, and fixed me to the ground. The wind was so violent that anchors or ropes would have been of no service. I had however added to the large aerostatic globe a smaller one, of 60 pounds ascensional force, which would have contributed to fix me, when once I let it loose; but, notwithstanding this precaution, the men's assistance was very necessary to me. The parachute was yet wavering in the air, and did not come down till 12 minutes after."

"I performed my 27th ascension at Leipsick the 29th of September, in the midst of an incredible number of spectators, forming one of the most brilliant assemblies I ever beheld. The sky was as clear and serene as possible, and the air so calm that many of my friends, and multitudes of others, could follow me on horseback, and even on foot. I was sometimes so near them that they thought they could reach

me, but I could soon find the means of rising; and once, when they had actually taken hold of the cords, to see me float with the strings in their hands, I suddenly cut them, and mounted again in the air. All these amusing evolutions were in sight of the town and its environs. At length I yielded to the earnest solicitations of the company, and entered the town. The next day I emptied the inflammable air into another globe, with which I intended to try some experiments; and I let it off with a cradle, in which a dog was fixed. The balloon, having reached a considerable height, made an explosion in its under part, as I had imagined it would, having previously disposed it in a proper manner for that purpose; by which means the little animal fell gently to the ground."

"The day before yesterday having repeated this experiment, I prepared the globe in such a manner as to cause an explosion in its upper part, and added a parachute with two small dogs fixed to it. They went so high that, notwithstanding the serenity of the sky, the balloon was lost in its immense expanse. Telescopes of the best sort became useless, and I began to be apprehensive for the death of the little animals, on account of the severity of the cold. They descended however about two hours after, quite safe and well, in the town of Delitzsch, 3 miles from Leipsick. I went yesterday to claim them, and found them again over the town in the air with the parachute. Such experiments had been already tried many times in the course of the day, and some officers had thrown them from the top of a steeple, in the sight of all the inhabitants, of Delitzsch, from which they descended safe."

We shall conclude this historical sketch with a short account of the aerial voyages performed by M. Garnerin, in London, in 1802. His first ascent in London was on June 29th, accompanied by Captain Sowden: they rose from Ranelagh, and alighted near Colchester, in less than three quarters of an hour, having in that short period travelled full 60 miles. During this voyage the aeronauts did not experience any inconvenience from the rapidity of their motion, until they began to descend, when they were much affected by the boisterousness of the wind: their descent was attended with danger, and occupied some minutes.

On the 21st of September, M. Garnerin undertook the singular and desperate experiment of ascending with an air balloon, and descending in a parachute. He ascended from St. George's Parade, North Audley-street, and descended safe into a field near the small-pox hospital at Pancras. The balloon was as usual made of oiled silk, covered with a net, from which ropes proceeded that terminated in, or were fixed to, a single rope, a few feet below the balloon, and to this rope the parachute was fastened in the following manner.

The parachute was about 30 feet in diameter; and several ropes of about 30 feet in length, which proceeded from its edge, terminated in a common joining, from which shorter ropes proceeded, and to the extremities of these a circular basket was attached, in which M. Garnerin placed himself. Now the single rope that has been said above to proceed from the balloon, passed through a hole in the centre of the parachute, and through tin tubes, which were placed one after another, and was lastly fastened to the basket; so that when the balloon was in the air, by cutting this rope, the parachute with the basket would be separated from it, and in falling downwards would naturally open by the resistance of the air. The

use of the tin tubes was to let the rope slip off with the greater certainty, and to prevent it from getting entangled with any part of the machinery belonging to the balloon.

About 6 o'clock, every thing being ready, M. Garnerin placed himself in the basket, and ascended majestically amidst the acclamations of innumerable spectators. The weather was the clearest and pleasantest imaginable, the wind blew a gentle breeze from w by s, and in about 8 minutes the balloon and parachute had ascended to an immense height, when M. Garnerin, in the basket, could scarcely be perceived. While every spectator was contemplating the grand sight before them, M. Garnerin cut the rope, and in an instant he was separated from the balloon, trusting his safety to the parachute. At first, viz, before the parachute opened, he fell with a great velocity; but as soon as it was expanded, which took place almost immediately after, the descent became very gentle and gradual.

In this descent a remarkable circumstance was observed, namely, that the parachute with the appendage of cords and basket, soon began to vibrate like the pendulum of a clock, and the vibrations were so great, that more than once the basket with M. Garnerin seemed to lie horizontally, which to the spectators appeared extremely dangerous: however, the extent of the vibrations diminished as he approached the ground. On coming to the earth the aeronaut experienced some pretty severe shocks, and when he came out of the basket he was much discomposed; but he soon recovered his spirits, and sustained no material injury from this desperate undertaking.

For several figures of balloons, see plate 1.

Practice of AEROSTATION. The first consideration in the practice of aerostation, is the form and the size of the machine. Various shapes have been tried and proposed, but the globular, or the egg-like figures, are the most proper and convenient, for all purposes; and this form also will require less cloth or silk than any other shape of the same capacity; so that it will both come cheaper, and have a greater power of ascension. The bag or cover of an inflammable-air balloon, is best made of the silk stuff called lustering, varnished over. But for a montgolfier, or heated-air balloon, on account of its great size, linen cloth has been used, lined within or without with paper, and varnished. Small balloons are made either of varnished paper, or simply of paper unvarnished, or of gold-beater's skin, or such-like light substances.

With respect to the form of a balloon, it will be necessary that the operator remember the common proportions between the diameters, circumferences, surfaces, and solidities of spheres; for instance, that of different spheres, the circumferences are as the diameters; that the surfaces are as the squares of the diameters; and the solidities as the cubes of the same: that any diameter is to its circumference as 7 to 22, or as 1 to $\frac{3}{7}$; so that if the diameter of a balloon be 35 feet, its circumference will be 110 feet. And if the diameter be multiplied by the circumference, the product will be the surface of the sphere; thus 35 multiplied by 110 gives 3850, which is the surface of the same sphere in square feet: and if this surface be divided by the breadth of the stuff, in feet, which the balloon is to be made of, the quotient will be the number of feet in length necessary to construct the balloon; so if the stuff be 3 feet wide, then 3850 divided by 3, gives 1283 $\frac{1}{3}$ feet, or 428 yards nearly, the requisite quantity of yard-wide

stuff, to form the balloon of 35 feet diameter. Hence also, by knowing the weight of a given piece of the stuff, as of a square foot, or square yard, it is easy to find the weight of the whole bag, namely by multiplying the surface, in square feet or yards, by the weight of a square foot or yard: so if each square yard weigh 1 pound, then the whole bag will weigh 428 pounds. Again, the capacity, or solid contents, of the sphere, will be found by multiplying $\frac{4}{3}$ of the surface by the diameter; which gives 22458 cubic feet for the capacity of the said balloon, that is, it will contain, or displace, 22458 cubic feet of air. From the content and surface of the balloon, so found, is to be derived its power of ascension, thus: On an average, a cubic foot of common air weighs 1 $\frac{1}{2}$ ounce, and therefore to the number 22458, which is the content of our balloon, adding its $\frac{1}{2}$ part, we have 26950 ounces, or 1684 pounds, for the weight of the common air displaced or occupied by the balloon. From this weight must be deducted the weight of the bag, namely 428 pounds, and then there remains a power of 1256 pounds.

If inflammable air be used, as it is of different weights, from $\frac{2}{3}$ to $\frac{1}{10}$ or $\frac{1}{15}$ the weight of common air, according to the modes of preparing it: let us suppose for instance, that it is $\frac{1}{3}$ of the weight of common air; then $\frac{1}{3}$ of 1684 is 261 pounds, which is the weight of the bag full of that air; which being taken from 1256, leaves 995 pounds for the power of the balloon when so filled with that inflammable air, or the weight which it will carry up, consisting of the car, the ropes, the passengers, ballast, &c. But if heated air be used; then as it is known from experiment that, by heat, the contained air is diminished in density about one-third only, therefore from 1684, take $\frac{2}{3}$ of itself, and there remains 1123 for the weight of the contained warm air; and this being subtracted from 1256, leaves only 133 pounds for the power of the balloon in this case; which being too small to carry up the car, passengers, &c, it shows that for those purposes a larger balloon is necessary, on Montgolfier's principles. But if now, from the preceding computation, it be required to find how much the size of the balloon must be increased, that its power of ascension may be equal to any given weight, as suppose 1000 pounds; then because the powers are nearly as the cubes of the diameters, therefore the diameters will be nearly as the cube roots of the powers; but 133 and 1000 are nearly as 1 to 8, the cube roots of which are as 1 to 2, and consequently 1 : 2 :: 35 : 70 feet, which is the diameter of a montgolfier, made of the same thickness of stuff as the former, capable of lifting 1000 pounds.

On the same principles we can easily find the size of a balloon that shall just float in air when made of stuff of a given thickness or weight, and filled with air of a given density; the rule for which is this: From the weight of a cubic foot of common air, subtract that of a cubic foot of the lighter or contained air; then divide 6 times the weight of a square foot of the stuff, by the remainder; and the quotient will be the diameter, in feet, of the balloon that will just float at the surface of the earth. Suppose, for instance, that the materials are as before, namely, the stuff 1 pound to the square yard, or $\frac{1}{2}$ ounces to the square foot, which taken 6 times is $\frac{3}{2}$; then the cubic foot of common air weighing 1 $\frac{1}{2}$ ounce, and of heated air $\frac{2}{3}$ of the same, whose difference is $\frac{1}{3}$; therefore $\frac{3}{2}$ divided by $\frac{1}{3}$, gives $26\frac{2}{3}$ feet, which is the diameter of a montgolfier that will just float: but if inflammable air be

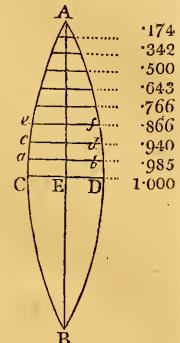

used of $\frac{1}{6}$ the weight of common air, the difference between $1\frac{1}{2}$ and $\frac{1}{6}$ of it, is 1; by which dividing $\frac{3}{7}$ or $10\frac{2}{7}$, the quotient is the same $10\frac{2}{7}$ feet, which therefore is the diameter of an inflammable-air balloon that will just float. And if the diameter be more than these dimensions, the balloons will ascend into the atmosphere.

An estimate of the height to which a given balloon will rise in the atmosphere, may be made as follows: having given only the diameter of the balloon, and the weight which just balances it, or that is just necessary to keep it from rising: compute the capacity or content of the globe in cubic feet, and divide its restraining weight in ounces by that content, then the quotient will be the difference between the density or specific gravity of the atmosphere at the earth's surface, and that at the height to which the balloon will rise; therefore subtract that difference or quotient from $1\frac{1}{2}$ or 1.2, the density at the earth's surface, and the remainder will be the density at that height: then the height answering to that density will be found sufficiently near in the annexed table. Thus, in the foregoing examples, in which the diameter of the balloon is 35 feet, its capacity 22458, and the power of the first 995 pounds, or 15920 ounces, the quotient of the latter number divided by the former, is .709, which is the density at the utmost height, and to which in the table answers a little more than $2\frac{1}{2}$ miles, or $2\frac{1}{2}$ miles nearly, which therefore is the height to which the balloon will ascend. And when the same balloon was filled with heated air, its power was found equal to only 133 pounds, or 2128 ounces, and dividing this by 22458 the capacity, the quotient .095 taken from 1.200, leaves 1.105 for the density; which in the table corresponds to half a mile, or nearer $\frac{2}{3}$ of a mile. And so high would these balloons ascend, if they keep the same figure, and lost none of the contained air; or rather, those are the heights they would settle at: for their acquired velocity would first carry them above that height, so far as till all their motion should be destroyed; then they would descend and pass below that height, but not so much as they had gone above; after which they would re-ascend, and pass that height again, but not so far as they had gone below it; and so on for many times, vibrating alternately above and below that point, but always less and less every time. The foregoing rule, for finding the height to which the balloon will ascend, is independent of the different states of the thermometer at that highest point, and at the surface of the earth; but for greater accuracy, including the allowances depending on the different states of the thermometer, see under the word ATMOSPHERE, where the more accurate rules are given at large.

The best way to make up the whole coating of the balloon, is by different pieces or slips joined lengthways from end to end, like the pieces composing the surface of a geographical globe, and contained between one meridian and another, or like the slices into which a melon is usually cut, and supposed to be spread flat out. Now the edges of such pieces cannot be exactly described by a pair of compasses, not being circular, but flatter or less round than circular arches; but if the slips are sufficiently nar-

row, or numerous, they will differ the less from circles and may be described as such. But more accurately, the breadths of the slip, at the several distances from the points to the middle, where it is broadest, are directly as the sines of those distances, radius being the sine of the half length of the slip, or of the distance of either point from the middle of the slip: that is, If $A C B D$ be one of the slips, $A B$ being half the circumference, or $A E$ a quadrant conceived to be equal to AC or AD ; then will CD be to AB , as radius or the sine of AC , to the sine of AA . So that if the quadrant $A E$ or AC be divided into any number of equal parts, as here suppose 9, then divide the quadrant or 90 degrees by the number of parts 9, and the quotient 10 is the number of degrees in each part; and hence the arcs AC , AA , AC , &c, will be respectively 90° , 80° , 70° , &c; and, CD being radius, the several breadths ab , cd , ef , &c, will be respectively the sines of 80° , 70° , 60° , &c, which are here placed opposite to them, the radius being 1. Therefore, when it is proposed to cut out slips for a globe of a given diameter; compute the circumference, and make $A E$ or AC a quarter of that circumference, and CD of any breadth, as 3 feet, or 2 feet, or any other quantity; then multiply each of the decimal numbers, set opposite the figure, by that quantity, or breadth of CD , so shall the products be the several breadths ab , cd , ef , &c.

Various schemes have been devised for conducting balloons in any direction, whether vertical or sideways. As to the vertical directions, namely upwards or downwards, the means are obvious, viz, in order to ascend, the aeronaut throws out some ballast; and that he may descend, he opens a valve in the top of his machine by means of a string, to let some of the gas escape; or if it be a montgolfier, he increases or diminishes the fire, as he would ascend or descend. But to direct the machine in a side or horizontal course, is a very difficult operation, and what has hitherto not been accomplished, except in a small degree, and when the current of air is very gentle indeed. The difficulty of moving the balloon sideways, arises from the want of wind blowing upon it; for as it floats along with the current of air, it is relatively in a calm, and the aeronaut feels no more wind than if the machine were at rest in a perfect calm. For this reason, any thing in the nature of sails can be of no use; and all that can be hoped for, is to be attempted by means of oars; and how small the effect of these must be, may easily be conceived from the rarity of the medium against which they must act, and the great magnitude of the machine to be forced through it. We can easily assign what force is necessary to move a given machine in the air with any proposed velocity. From very accurate experiments I have determined, that a globe of $6\frac{2}{3}$ inches in diameter, and moving with a velocity of 20 feet per second of time, suffers a resistance from the air which is just equal to the weight or pressure of one ounce Averdupois; and further, that with different surfaces, and the same velocity, the resistances are directly proportional to the surface nearly, a

double surface having a double resistance, a triple surface a triple resistance, and so on; and also, that with different velocities, the resistances are proportional to the squares of the velocities nearly, so that a double velocity produced a quadruple resistance, and 3 times the velocity 9 times the resistance, and so on. And hence we can assign the resistance necessary to move a given balloon, with any velocity. Thus, take the balloon as before of 35 feet diameter; then by comparison as above it is found that this globe, if moved with the velocity of 20 feet per second, or almost 14 miles per hour, will suffer a resistance equal to 271 pounds; to move it at the rate of 7 miles an hour, the resistance will be 68 pounds; and to move it $\frac{3}{2}$ miles an hour, the resistance will be 17 pounds; and so on; and with such force must the aeronauts act on the air in a contrary direction, to communicate such a motion to the machine. But, if the balloon move through a rarer part of the atmosphere, than that at the surface of the earth, as $\frac{2}{3}$, or $\frac{1}{2}$, &c, rarer, and consequently the resistance be less in the same proportion; yet the force of the oars will be diminished as much; and therefore the same difficulty still remains. In general, the aeronaut must strike the air, by means of his oars, with a force just equal to the resistance of the air on the balloon, and therefore he must strike that air with a velocity which must be greater as the surface of the oar is less than the resisted surface of the globe, but not in the same proportion, because the force is as the square of the velocity.

Now, suppose the aeronaut act with an oar equal to 100 square feet of surface, to move the balloon above mentioned at the rate of 20 feet per second, or 14 miles an hour; then must he move this oar with the great velocity of 62 feet per second, or near 43 miles per hour: and so in proportion for other velocities of the balloon. Whence it is highly probable, that it will never be in the power of man to guide such machine with any tolerable degree of success, especially when any considerable wind blows, which is almost always the case.

The compositions for varnishing balloons have been variously modified; but upon the whole, the most approved appears to be the bird-lime varnish of M. Faujas St. Fond. Mr. Blanchard used a varnish made of elastic resin, known commonly by the name of India rubber, dissolved in five times its weight of rectified essential oil of turpentine; which is also held in great esteem.

The methods of obtaining inflammable air for filling balloons is generally, by applying acids to certain metals, by exposing animal, vegetable, and some mineral substances, in a close vessel to a strong fire, or, by transmitting the vapour of certain fluids through red-hot tubes.

In the first of these methods, iron, zinc, and vitriolic acid, are the materials most generally used. The vitriolic acid must be diluted by five or six parts of water. Iron may be expected to yield in the common way 1700 times its own bulk of gas; or one foot of inflammable air to be produced by $4\frac{1}{2}$ ounces of iron, the same weight of oil of vitriol, and $2\frac{1}{2}$ ounces of water. Six ounces of zinc, an equal weight of oil of vitriol, and 30 ounces of water, are necessary for producing the same quantity of gas.

And here it should be observed, that the turnings or chippings of great pieces of iron, as of cannons, &c, are preferable to the filings of that metal. The weight of the inflammable air thus obtained, by means of acid of vitriol, is in the common way of procuring it, generally about one seventh part of the weight of common

air; but with the necessary precautions, for philosophical experiments, less than one tenth of the weight of common air. Two other sorts of elastic fluids are sometimes generated with the inflammable air, which may be separated from it, by passing the gas through water, in which quick lime has been dissolved. The water will absorb these fluids, cool the inflammable air, and prevent its over heating the balloon when introduced into it.

Inflammable air may be obtained at a much cheaper rate by the action of fire upon various substances; but the gas that they yield is not so light as that produced by the effervescence of acids and metals. The substances proper for this are, pit-coal, asphaltum, amber, rock-oil, and other minerals; wood and particularly oak, camphor-oil, spirits of wine, ether, and animal substances; all of which yield air in different degrees, and of various specific gravities: but pit-coal is the preferable substance.

Another method of obtaining inflammable air was discovered by M. Lavoisier, and also by Dr. Priestley; which is, by making the steam of boiling water pass through the barrel of a gun, kept red-hot by burning coal. Dr. Priestley used, instead of the gun barrel, a red-hot tube of brass, upon which the steam of water has no effect; and which he filled with the pieces of iron separated by the boring of cannon; and by this means he obtained an inflammable air $\frac{1}{3}$ part the weight of common air. But of these three methods, the former is the only one that can be safely depended on for obtaining proper gas for filling large balloons; and here it has been recommended to use zinc instead of iron turnings, because the white vitriol, the salt produced by the union of the vitriolic acid and zinc, is much more valuable than the green sort produced by the union of the same acid with iron. But though this is undoubtedly the case, it will certainly be found upon trial, that the superior price of the zinc, will be more than an equivalent for all the advantage that can be derived from the additional price of the white vitriol.

The method of filling balloons, being merely mechanical, is omitted in this place; but ample information on this, and many other particulars, may be met with in several books expressly written on the subject; as in Cavallo's History and Practice of Aerostation, 8vo, 1785; in Baldwin's Airopaidia, 8vo, 1786; and the Description des Experiences, &c, par M. Faujas St. Fond. See also an ingenious and learned treatise on the mathematical and physical principles of Air-balloons, by the late Dr. Damen, professor of philosophy and mathematics in the University of Leyden, entitled, Physical and Mathematical Contemplations on Aerostatic Balloons, &c; in 8vo, at Utrecht, 1784.

It has often been discussed, says the former of these gentlemen, whether the preference should be given to machines raised by inflammable air, or to those raised by heated air. Each of them has its peculiar advantages and disadvantages; a just consideration of which seems to decide in favour of those made with inflammable air. The principal comparative advantages of the other sort are, that they do not require to be made of so expensive materials; that they are filled with little or no expense; and that the combustibles necessary to fill them are found almost every where; so that, when the stock of fuel is exhausted, the aeronaut may descend and recruit it again, in order to proceed on his voyage. But then this kind of machines must be made larger than the other, to take up

the same weight; and the presence of a fire is a continual trouble, as well as danger: in fact, among the many aerial voyages that have been made and attempted with such machines, very few have succeeded without an inconvenience, or an accident; and some indeed have been attended with dangerous and even fatal consequences; from which the other kind is in a great measure exempt. But, on the other hand, the inflammable-air balloon must be made of a substance impermeable to the subtle gas: the gas itself cannot be produced without a considerable expense; and it is not easy to find the materials and apparatus necessary for the production of it in every place. However, it has been found that an inflammable-air balloon, of 30 feet in diameter, may be made so close as to sustain two persons, and a considerable quantity of ballast, in the air for more than 24 hours, when properly managed; and possibly one man might be supported by the same machine for three days: and it is probable that the stuff for these balloons may be so far improved, as to be quite impermeable to the gas, or very nearly so; in which case, the machine, once filled, would continue to float for long time. At Paris they have already attained to a great degree of perfection in this point; and small balloons have been kept floating in a room for many weeks, without losing any considerable quantity of their levity: but the difficulty lies in the large machines: for in these, the weight of the stuff itself, with the weight and stress of the ropes and boat, and the folding them up, may easily crack and rub off the varnish, and make them leaky.

With regard to the uses to which balloons can be applied, it must be observed, that the perfection of all arts, and the application of them to the useful purposes of man, have always been progressive, and not the immediate result of a fortunate discovery; if therefore at present no great advantages have been derived from the art of aeronautics, we ought not to despair, nor discourage any future attempts, which it is to be hoped may prove more successful in this respect. But even in the present incomplete state of this art, some advantages have been derived from it. Thus, the French ascribe to the elevation of a balloon, and the information obtained in consequence of thus reconnoitring the army of the enemy, the signal victory gained in the battle of Fleurus in 1794. Balloons may likewise serve to explore and ascertain the nature of the air in the higher regions of the atmosphere. One of the finest experiments made on this point, is that of Gay-Lusac, who being elevated in a balloon to the height of nearly eight miles, the greatest ever attained by any person, brought some atmospheric air from those regions, which, on being analysed, was found to furnish the principles of oxygen, azote, hydrogen, and carbonic acid gas, in the same proportions as at the surface of the earth. In fact, the application of these machines to the advancement of our knowledge of the various phenomena in meteorology, stands prominent, as perhaps the only means of maturing our acquaintance with causes yet known only by their effects.

ÆSTIVAL, see *ESTIVAL*.

ÆSTUARY, or *ESTUARY*, in Geography, an arm of the sea, running up a good way into the land. Such as Bristol channel, many of the friths in Scotland, and such-like.

ÆTHER, see *ETHER*.

AFFECTED, or *AFFECTED*, *EQUATION*, in Algebra,

is an equation in which the unknown quantity rises to two or more several powers or degrees. Such, for example, is the equation $x^3 - px^2 + qx = r$, in which there are three different powers of x , namely, x^3, x^2 , and x .

The term, affected, is also used sometimes in algebra, when speaking of quantities that have coefficients. Thus, in the quantity $2a$, a is said to be affected with the coefficient 2. It is also said, that an algebraic quantity is affected with the sign + or -, or with a radical sign; meaning no more than that it has the sign + or -, or that it includes a radical sign. The term affected, or affected, I think, was introduced by Vieta.

AFFECTION, in Geometry, a term used by some ancient writers, signifying the same as property.

AFFECTION. *Phys.* The affections of a body are certain modifications occasioned or induced by motion; in virtue of which the body is disposed after such or such a manner.

The affections of bodies, are sometimes divided into primary and secondary.

Primary Affections, are those which arise either out of the idea of matter, as magnitude, quantity, and figure; or out of the idea of form, as quality and power; or out of both, as motion, place, and time.

Secondary, or derivative Affections, are such as arise out of primary ones, as divisibility, continuity, contiguity, &c, which arise out of quantity; regularity, irregularity, &c, which arise out of figure, &c.

AFFINITY, in natural philosophy, the tendency which the particles of matter have to be attracted, or united to each other.

AFFIRMATIVE QUANTITY, or *POSITIVE QUANTITY*, one which is to be added, or taken effectively; in contradistinction to one that is to be subtracted, or taken defectively.—The term affirmative was introduced by Vieta.

AFFIRMATIVE SIGN, or *POSITIVE SIGN*, in Algebra, the sign of addition, thus marked +, and is called *plus*, or *more*, or *added to*. When set before any single quantity, it serves to denote that it is an affirmative or a positive quantity; when set between two or more quantities, it denotes their sum, showing that the latter are to be added to the former. So + 6, and + a , and + ab , are affirmative quantities; also 6 + 8 + 10 denote the sum of 6, 8, and 10, which is 24, and are read thus, 6 plus 8 plus 10. Also $a + b + c$ denote the sum of the quantities represented by a , b , and c , when added together. It seems now not easy to ascertain with certainty, when, or by whom, this sign was first introduced; but it was probably by the Germans, as I find it first used by Stifelius in his Arithmetic, printed in 1544. When quantities are set down without a prefixed sign, as a , or b , or x , &c, they are understood to be affirmative ones.

The early writers on Algebra used the word *plus* in Latin, or *più* in Italian, for addition, and afterwards the initial *p* only, as a contraction; like as they used *minus*, or *meno*, or the initial *m* only, for subtraction: and thus these operations were denoted in Italy by Lucas de Burgo, Tartalea, and Cardan, while the signs + and - were employed much about the same time in Germany by Stifelius, Scheubelius, and others, for the same operations.

AGE, in Chronology, is used for a century, being a system or period of a hundred years.

Chronologists also divide the time since the creation of the world into three ages: The first, from Adam to Moses, which they call the age of nature; the second from

Moses to Jesus Christ, called the age of the law; and the third, or age of grace, from Jesus Christ till the end of the world.

AGE of the Moon, in Astronomy, is the number of days elapsed since the last new moon. To find the moon's age, for any time nearly, for ordinary uses; add together the epact, the day of the current month, and the number of months from March to the present month inclusive; the sum is the moon's age: but if the sum exceed 29, deduct this number from it in months that have 30 days, or 30 in those that have 31; and the remainder will be the age. —At the end of 19 years the moon's age returns upon the same day of the month, but falls a little short of the same hour of the day.

AGENT, *Agens*, in Physics, that by which a thing is done or effected; or any thing having a power by which it acts on another, called the object.

AGGREGATE, the sum or result of several things added together. See **SUM**.

AGITATION, in Physics, a brisk intestine motion, excited among the particles of a body. Thus, fire agitates the subtlest particles of bodies. Fermentations, and effervescences, are produced by a brisk agitation of the particles of the fermenting body.

AGNESI (Maria Gaetana), an Italian young lady, highly celebrated for her learning and talents. Signora Agnesi was born at Milan in 1718, and by her genius and industry soon became profoundly learned in several languages, as well as in the mathematical and philosophical sciences. While very young she composed an excellent treatise on the doctrine of fluxions, which was published at Milan 1748, under the title of *Analytical Institutions*, in 2 volumes 4to; a very useful work, which was honoured by a French translation, at Paris, by Cousin, in 1775; and by an English translation, made many years since by the late professor Colson, of Cambridge, and lately published at the expense of Mr. Baron Maseres, under the care of the Rev. John Hollins, in 2 vols. 4to, 1801. In just consideration of such eminent qualifications, S. Agnesi was appointed public professor of mathematics at Bologna in 1750, an office which she discharged with the greatest credit for some time.

It is with regret however we add, that neither her inclination for those honourable intellectual pursuits, nor a desire of preserving and increasing the celebrity she had obtained, nor the entreaties of her family and friends, could prevent her from devoting herself to a monastic life, among the sisters known by the name of the Blue Nuns. From the period of her retiring to the cloister, it may be concluded that her life was not chequered with any variety of incidents. Accordingly, we only further learn that this illustrious ornament of her sex died about the year 1770.

AGUILON, or **AQUILON**, (Francis), was a jesuit of Brussels, and professor of philosophy at Doway, and of theology at Antwerp. He was one of the first that introduced mathematical studies into Flanders. He wrote a large work on Optics, in 6 books, which was published in folio, at Antwerp, in 1613; and a treatise of Projections of the Sphere. He promised also to treat upon Catoptrics and Dioptrics; but this was prevented by his death, which happened at Seville, in the year 1617.

AIR, in Natural Philosophy and Chemistry, a general term used to denote such invisible rare fluids as possess a very high degree of elasticity, and are not condensable

into a visible fluid by any degree of cold; in this respect air is distinguished from vapour, which may be thus condensed.

This term was originally applied to the air of which our atmosphere is composed, and considered by the ancients as a simple element; but the researches of modern chemists have shown it to be a compound, and that it may be resolved into its several component parts, (see **GAS**); but at present we shall only consider it as relating to the atmosphere, without entering into its chemical properties.

Air, Atmospheric, is an invisible, insipid, inodorous, heavy, and elastic fluid, possessing great mobility, susceptible of rarefaction, and of condensation; it surrounds the terrestrial globe to a certain height, the entire mass constituting the atmosphere. The consideration of this fluid cannot but be a highly interesting subject, since it is the depository of the signs of our thoughts and our affections; at the same time, that it serves for the preservation of life in every animated being.

Mechanical Properties and Effects of AIR. Of these the most considerable are its fluidity, its weight, and its elasticity.

1. *Its Fluidity*.—The great fluidity of the air is manifest from the facility with which bodies traverse it; as in the propagation of, and easy conveyance it affords to, sounds, odours and other effluvia and emanations that escape from bodies: for these effects prove that it is a body whose parts give way to any force, and in yielding are easily moved among themselves; which is the definition of a fluid. That the air is a fluid is also proved from this circumstance, that it is found to exert an equal pressure in all directions; an effect which could not take place otherwise than from its extreme fluidity. Neither has it been found that the air can be deprived of this property, whether it be kept for many years together confined in glass vessels, or be exposed to the greatest natural or artificial cold, or condensed by the most powerful pressure; for in none of these circumstances has it ever been reduced to a solid state.

2. *Its Weight or Gravity*.—The weight or gravity of the air, is a property belonging to it as a body; for gravity is a property essential to matter, or at least a property found in all bodies. But independent of this, we have many direct proofs of its gravity from sense and experiment: thus, the hand laid close upon the end of a vessel, out of which the air is drawn at the other end, soon feels the load of the incumbent atmosphere: thus also, two hollow segments of a sphere, of about 4 inches in diameter, exactly fitting each other, being emptied of air, are, by the weight of the ambient air, pressed together with a force which requires the weight of 188 pounds to separate them; and that they are thus forcibly held together by the pressure of the air, is made evident by suspending them in an exhausted receiver, for then they quickly separate of themselves, and fall asunder. Again, if a tube, close at one end, be filled with quicksilver, and the open end be immersed in a bason of the same fluid, and so held upright, the quicksilver in the tube will be kept raised up in it to the height of about 30 inches above the surface of that in the bason, being supported and balanced by the pressure of the external air upon that surface: and that this is the cause of the suspension of the quicksilver in the tube, is made evident by placing the whole apparatus under the receiver of an air-pump; for then the

fluid descends in the tube in proportion as the receiver is exhausted of its air; and on gradually letting in the air again, the quicksilver reascends to its former height: and this is the common barometer, or what is called, from its inventor, the Torricellian experiment. Nay farther, air can actually be weighed like any other body: for a rigid vessel, full even of common air, by a nice balance is found to weigh more than when the air is exhausted from it; and the effect is proportionally more sensible, if the vessel be weighed full of condensed air, and more still if it be weighed in a receiver void of air.

But, though we have innumerable proofs of the gravitating property of the air, yet the full discovery of the laws and circumstances of it are certainly due to the moderns. It cannot indeed be denied, that several of the ancients had some confused notions about this property: thus Aristotle says, that all the elements have gravity, and even air itself; and as a proof of it, says that a bladder inflated with air, weighs more than the same when empty; and Plutarch and Stobaeus quote him as teaching that the air in its weight is between that of fire and of earth; and farther, he himself, treating of respiration, reports it as the opinion of Empedocles, that he ascribes the cause of it to the weight of the air, which by its pressure forces itself into the lungs; and much in the same way are the sentiments of Asclepiades expressed by Plutarch, who represents him as saying, among other things, that the external air, by its weight, forcibly opened its way into the breast. But nevertheless it is certain, however unreasonable it may seem, that Aristotle's followers departed in this instance from their master, by asserting the contrary for many ages together. Indeed several of the phenomena arising from this property, have been remarked from the highest antiquity. Many centuries since, it was known that by sucking the air from an open pipe, having its extremity immersed in water, this fluid rises above its level, and occupies the place of the air. In consequence of such observations, sucking pumps were contrived, and various other hydraulic machines; as Heron's syphons, described in his *Spiritalia* or *Pneumatics*, and the watering-pots known in Aristotle's time under the name of *cleypsydrae*, which alternately stop or run as the finger closes or opens their upper orifice. Indeed the reason assigned, by philosophers many ages after, for this phenomenon, was a pretended horror that nature conceives for a vacuum, which, rather than endure it, makes a body ascend contrary to the powerful solicitation of its gravity. Even Galileo, with all his sagacity, could not for some time hit upon any thing more satisfactory; for he only assigned a limit to this dread of vacuity: having observed that sucking pumps would not raise water higher than 16 brasses, or 34 English feet, he limited this abhorring force of nature, to one that was equivalent to the weight of a column of water 34 feet high, on the same base as the void space. Consequently he pointed out a way of making a vacuum, by means of a hollow cylinder, whose piston is charged with a weight sufficient to detach it from the close bottom turned upwards: this effort he called the measure of the force of vacuity, and made use of it for explaining the cohesion of the parts of bodies.

Galileo, however, was well apprised of the weight of the air as a body: in his *Dialogues* he shows two ways of demonstrating it, by weighing it in bottles: the transition was easy from one discovery to another: yet still Galileo's knowledge of the matter was imperfect, that is, as to

the particular instance of the suspension of a fluid above its level, by the pressure of the external air.

At length, Torricelli conceived the happy idea, that the counterpoise which keeps fluids above their level, when nothing presses upon their internal surface, is the mass of air resting upon the external one. He discovered it in the following manner: In the year 1643 this disciple of Galileo, on occasion of executing an experiment on the vacuum formed in pumps, above the column of water, when it exceeds 34 feet, thought of using some heavier fluid, such as quicksilver. He conceived, that whatever might be the cause by which a column of water of 34 feet high is sustained above its level, the same force would sustain a column of any other fluid, which weighed as much as that column of water, on the same base; whence he concluded that quicksilver, being about 14 times as heavy as water, would not be sustained higher than 29 or 30 inches. He therefore took a glass tube of several feet in length, sealed it hermetically at one end, and filled it with quicksilver; then inverting it, and holding it upright, by pressing his finger against the lower or open orifice, he immersed that end in a vessel of quicksilver; when removing his finger, and suffering the fluid to run out, the event verified his conjecture; the quicksilver, faithful to the laws of hydrostatics, descended till the column of it was about 30 inches high above the surface of that in the vessel below. And hence Torricelli concluded, that it was no other than the weight of the air incumbent on the surface of the external quicksilver, which counterbalanced the fluid contained in the tube.

By this experiment Torricelli not only proved, what Galileo had done before, that the air had weight, but also that it was its weight which kept water and quicksilver raised in pumps and tubes, and that the weight of the whole column of it was equal to that of a like column of quicksilver of 30 inches in height, or of water 34 or 35 feet high; but he did not ascertain the weight of any particular quantity of it, as a gallon, or a cubic foot of it, nor its specific gravity to water, which had been done by Galileo, though to be sure with no great accuracy, for he only proved that water was more than 400 times heavier than air.

Father Mersenne, who kept up a correspondence with most of the literati in Italy, was informed of Torricelli's experiment in 1644, and communicated it to those of France, who presently repeated the experiment: Messrs. Pascal and Petit made it first, and varied it several ways; which gave occasion to the ingenious treatise which Pascal published at 23 years of age, entitled *Experiences Nouvelles touchant la Vuide*. In this treatise indeed he makes use of the old principle of *fuga vacui*; but afterwards getting some notion of the weight of the air, he soon adopted Torricelli's idea, and devised several experiments to confirm it. One of these was to procure a vacuum above the reservoir of quicksilver; in which case, he found the column sink down to the common level: but this appearing to him not sufficiently powerful to dissipate the prejudices of the ancient philosophy, he prevailed on M. Perier, his brother-in-law, to execute the celebrated experiment of Puy-de-Domme, who found that the height of the quicksilver half-way up the mountain was less, by some inches, than at the foot of it, and still less at the top: so that it was now put out of doubt, that it was the weight of the atmosphere which counterpoised the quicksilver.

Des Cartes too had a right notion of this effect of the air, to sustain fluids above their level, as appears by some of his letters about this time, and some years before; and in one of those he lays claim to the idea of the Puy-de-Domme experiment. After having desired M. de Carcavi to inform him of the success of the experiment, made by M. Pascal, he adds, "I had reason to expect this from him, rather than from you, because I first proposed it to him two years since, assuring him at the same time, that though I had not tried it, yet I could not doubt of the consequence; but as he is a friend of M. Roberval, who professes himself no friend to me, I suppose he is guided by that gentleman's passions." See more of this history under BAROMETER.

As to the actual weight of any given portion of common air, it seems that Galileo was the first who determined it experimentally; and he gives two different methods, in his Dialogues, for weighing it in bottles: he did not however perform the experiment very accurately, as he stated from the result that the gravity of water was to that of air rather above 400 to 1, as before said.

A quantity of air was next weighed by Mersenne in a very ingenious manner. His idea was to weigh a vessel both when full of air, and when emptied of it; to make the vacuum for this purpose, he knew no better way than by expelling the air out of an eolipile by heating it red-hot: by weighing it both when cold and hot, he found a certain difference; which however was not the exact weight of that capacity of air, because the vacuum was not perfect. For, by plunging the colipile, when red-hot, into water, just so much water entered as was equal in bulk to the air that had been expelled; he then took it out and weighed it with the water, which gave the weight of the same bulk of water; and on comparing this with the former difference, or weight of air expelled, he found their proportion to be as 1300 to 1; which is as wide of the truth as Galileo's proportion, namely 400 to 1, but the contrary way. And it is remarkable that the mean between the two, namely 850 to 1, happens to be very near the true proportion, as settled by other more accurate experiments.

Mr. Boyle, by a more accurate experiment, found the proportion to be that of 938 to 1. And Mr. Hauksbee found it as 850 to 1, proceeding on the same principles as Mersenne, with a three-gallon glass bottle, but extracting the air out of it with the air-pump, instead of expelling it by fire; the height of the barometer being at that time 29 $\frac{3}{4}$ inches. Also by other experiments made before the Royal Society by Mr. Hauksbee, Dr. Halley, Mr. Cotes, and others, the proportion was always between 800 and 900 to 1, but rather nearer the latter, namely, being first found as 840 to 1, then as 852 to 1, and a third time as 860 to 1; the barometer then standing at 29 $\frac{3}{4}$ inches, and the weather warm. Mr. Cavendish determines the ratio 800 to 1, the barometer being 29 $\frac{3}{4}$, and the thermometer at 50°; and Sir George Shuckburgh, by a very accurate experiment, finds it 836 to 1, the barometer being at that time 29 $\frac{2}{3}$, and the thermometer at 51°. The medium of all these is about 833 or 833 to 1, when reduced to the pressure of 30 inches of the barometer, and the mean temperature 55° of the thermometer. Upon the whole therefore, it may be safely concluded that, when the barometer is at 30 inches, and the thermometer at the mean temperature 55°, the density or gravity of water, is to that of air, as 833 $\frac{1}{2}$ to 1, that is as

$\frac{2500}{3}$ to 1, or as 2500 to 3; and that for any changes in the height of the barometer, the ratio varies proportionally; also that the density of the air is altered by the $\frac{1}{45}$ th part for every degree of the thermometer above or below temperate.

This number, which is a very good medium among them all, we have chosen with the fraction $\frac{1}{3}$, because it gives exactly 1 $\frac{1}{2}$ ounce for the mean weight of a cubic foot of air, the weight of the cubic foot of water being just 1000 ounces averdupois, and that of quicksilver equal to 13600 ounces.

Air, then, having been shown to be a heavy fluid substance, the laws of its gravitation and pressure must be the same as those of water and other fluids; and consequently its pressure must be proportional to its perpendicular altitude. Which is exactly conformable to experiment; for on removing the Torricellian tube to different heights, where the column of air is shorter, the column of quicksilver which it sustains is shorter also, and that nearly at the rate of 100 feet for $\frac{1}{30}$ of an inch of quicksilver. And on these principles depend the structure and use of the barometer.

From the same principle it likewise follows that air, like other fluids, presses equally in all directions. And hence it happens, that soft bodies endure this pressure without change of figure, and hard or brittle bodies without breaking; being equally pressed on all parts: but if the pressure be taken off, or diminished, on one side, the effect of it is immediately perceived on the other. See ATMOSPHERE, for the total quantity of effects and pressure, and the laws of different altitudes, &c.

From the weight and fluidity of the air, jointly considered, many effects and uses of it may easily be deduced. By the combination of these two qualities, it closely invests the earth, with all the bodies upon it, constringing and binding them down with a great force, namely a pressure equal to about 15 pounds upon every square inch. Hence, for example, it prevents the arterial vessels of plants and animals from being too much distended by the impetus of the circulating juices, or by the elastic force of the air so copiously abounding in them. For hence it happens, that on a diminution of the pressure of the air, in the operation of cupping, we see the parts of the body grow tumid, which causes an alteration in the circulation of the fluids in the capillary vessels. And the same cause hinders the fluids from transpiring through the pores of their containing vessels, which would otherwise cause the greatest debility, and often destroy the animal. To the same two qualities of the air, weight and fluidity, is owing the mixture of bodies contiguous to one another, especially fluids; for several liquids, as oils and salts, which readily mix of themselves in air, will not mix at all in vacuo. With many other natural phenomena.

3. Elasticity. Another quality of the air, from whence arises a multitude of effects, is its elasticity; a quality by which it yields to the pressure of any other bodies, by contracting its volume; and dilates and expands itself again on the removal or diminution of the pressure. This quality is the chief distinctive property of air, the other two being common to all fluids.

Of this property we have innumerable instances. Thus, for example, a blown bladder being squeezed in the hand, we find a sensible resistance from the included air; and, on taking off the pressure, the compressed parts immediately restore themselves to their former round figure.

And on this property of elasticity depend the structure and uses of the air-pump.

Every particle of air makes a continual effort to dilate itself, thus acting forcibly against all the neighbouring particles, which also exert the like force in return; but if their resistance happen to cease, or be weakened, the particle immediately expands to an immense extent. Hence it is that thin glass bubbles, or bladders, filled with air, and placed under the receiver of an air-pump, will, on pumping out the air, burst asunder by the force of the air which they contain. So likewise a close flaccid bladder, containing only a small quantity of air, being put under the receiver, swells as the receiver is exhausted, and at length appears quite full. And the same thing happens by carrying the flaccid bladder to the top of a very high mountain.

The same experiment shows that this elastic property of the air is very different from the elasticity of solid bodies, and that their dilatation arises from a different cause. For when air ceases to be compressed, it not only dilates, but occupies a far greater space, and exists under a volume immensely larger than before; whereas solid elastic bodies only resume their former figure.

It is plain that the weight or pressure of the air does not at all depend on its elasticity, and that it is neither more nor less heavy than if it were not at all elastic. But from its being elastic, it follows, that it is susceptible of a pressure, which reduces it to such a space, that the force of its elasticity, which re-acts against the pressing weight, is exactly equal to that weight. Now the law of the elasticity is such, that it increases in proportion to the density of the air, and that its density increases in proportion to the forces or weights which compress it. Now, there is a necessary equality between action and re-action; that is, the gravity of the air, which effects its compression, and the elasticity of it, which gives it its tendency to expansion, are equal.

So that, the elasticity increasing or diminishing, in the same proportion as the density increases or diminishes, that is, as the distances among its particles decrease or increase; it is no matter whether the air be compressed, and retained in any space, by the weight of the atmosphere, or by any other cause; as in either case it must endeavour to expand with the same force. And therefore, if such air as is near the earth be inclosed in a vessel, so as to have no communication with the external air, the pressure of such inclosed air will be exactly equal to that of the whole external atmosphere. And accordingly we find that quicksilver is sustained to the same height, by the elastic force of air inclosed in a glass vessel, as by the whole pressure of the atmosphere.—And on this principle of the condensation and elasticity of the air, depends the structure and use of the air-gun.

That the density of the air is always directly proportional to the force or weight which compresses it, was proved by Boyle and Mariotte, at least as far as their experiments go on this head: and Mr. Mariotte has shown that the same rule takes place in condensed air. However, this is not to be admitted as scrupulously exact; for when air is very forcibly compressed, so as to be reduced to $\frac{1}{5}$ th of its ordinary bulk, the effect does not answer precisely to the rule; for in this case the air begins to make a greater resistance, and requires a stronger compression, than is given by the above proportion. And hence it appears, that the particles of air cannot, by means of any

possible weight or pressure, however great, be brought into perfect contact, or that it cannot thus be reduced to a solid mass; and consequently, that there must be a limit to which this condensation of the air can never arrive. The same remark is true with regard to the rarefaction of air, namely, that in very high degrees of rarefaction, the elasticity is decreased rather more than in proportion to the weight or density of the air: and hence there must also be a limit to the rarefaction and expansion of the air, by which it is prevented from expanding to infinity.

To what degree air is susceptible of condensation, by compression, is not certainly known. Mr. Boyle condensed it 13 times more than in its natural state, by this means: others have compressed it into $\frac{1}{50}$ th part of its ordinary volume; Dr. Hales made it 38 times more dense, by means of a press; but by freezing water in a hollow cast-iron ball or shell, he reduced it to 1522 times less space than it naturally occupies; in which state it must have been of almost double the density or specific gravity of water: And as water is not compressible, except in a very small degree, it follows from this experiment, that the particles of air must be of a nature very different from those of water; since it would otherwise be impossible to reduce air to a volume above 800 times less than in its common state; there is however some reason to doubt of the accuracy of this experiment, as has been asserted by Dr. Halley, from some experiments performed in London, and others at Florence by the Academy del Cimento, that it may be safely concluded that no force whatever is capable to reduce air into a space 800 times less than that which it naturally occupies near the surface of the earth, at least by pressure. But others, and particularly M. Amontons, in the Memoirs of the French Academy, maintain, that there is no affixing any limits to its condensation; that greater and greater forces will reduce it into less and less compass; and that it is only elastic in virtue of the fire it contains; and that, as it is impossible ever absolutely to drive out all its fire, it is impossible ever to make the utmost condensation. We may further add, that the air contained in nitre, is probably condensed about 1600 times. See my Tracts, vol. 3, p. 303.

The elasticity of the air exerts its force equally in all directions; and when it is at liberty, and freed from the cause which compressed it, it expands equally on all sides, and in consequence always assumes a spherical figure in the interstices of the fluids in which it is lodged. This is evident in liquors placed in the receiver of an air-pump, by exhausting the air; at first there appears a multitude of exceeding small bubbles, like grains of fine sand, dispersed through the fluid mass, and rising upwards; and as more air is pumped out, they enlarge in size; but still they continue round. Also if a plate of metal be immersed in the liquor, on pumping, its surface will be seen covered over with small round bubbles, composed of the air which adhered to it, now expanding itself. And for the same reason it is that large glass globes are always blown up of a spherical shape, by blowing air through an iron tube into a piece of melted glass at the end of the pipe.

The expansion of the air, by virtue of its elastic property, when only the compressing force is taken off, or diminished, is found to be surprisingly great; and yet we are far from knowing the utmost dilatation of which it is capable. In several experiments made by Mr. Boyle, it

expanded first into 9 times its former space; then into 31 times; then into 60, and then into 150 times. Afterwards, it was brought to dilate into 8000 times its first space; then into 10000, and at last even into 13679 times its space; and all this solely by its own natural expansive force, by only removing the pressure, but without the help of fire. And on this principle depends the construction and use of the MANOMETER.

The elasticity of the air, under one and the same pressure, is still farther increased by heat, and diminished by cold, and that, by some late accurate experiments made by Sir George Shuckburgh, at the rate of the 440th part of its volume nearly, for each degree of the variation of heat, from that of temperate, in Fahrenheit's thermometer.

Mr. Hauksbee observed, that a portion of air inclosed in a glass tube, when the temperature was at the freezing point, formed a volume which was to that of the same quantity of air in the greatest heat of summer in England, as 6 to 7. And it has been found by several experiments, that air is expanded $\frac{1}{3}$ of its natural bulk by applying the heat of boiling water to it.

Dr. Hales found that the air in a retort, when the bottom of the vessel just became red-hot, was dilated into double its former space; and that in a white, or almost melting heat, it filled thrice its former space: but Mr. Robins found that air was expanded, by means of the white or fusing heat of iron, to 4 times its former bulk. See also several ingenious experiments on the elasticity of the air, in the Philos. Trans. for the year 1777, by Sir George Shuckburgh and Colonel Roy.

This properly explains the common effect observed on bringing a close flaccid bladder near the fire to warm it; when it is presently found to swell as if more air were blown into it. And on this principle depends the structure and office of the thermometer.

M. Amontons first discovered that, with the same heat, air will expand in a degree proportioned to its density. And on this foundation the ingenious author has formed a discourse, to prove "that the spring and weight of the air, with a moderate degree of warmth, may enable it to produce even earthquakes, and others of the most vehement commotions of nature." He computes, that at the depth of the 74th part of the earth's radius below the surface, the natural pressure of the air would reduce to the density of gold; and thence infers that all matter below that depth, is probably heavier than the heaviest metal that we know of. And hence again, as it is proved that the more the air is compressed, the more does the same degree of fire increase the force of its elasticity; we may infer that a degree of heat, which in our orb can produce only a moderate effect, may have a very violent one in such lower orb; and that, as there are many degrees of heat in nature, beyond that of boiling water, it is probable there may be some whose violence, thus assisted by the density of the air, may be sufficiently powerful to tear asunder the solid globe. Mem. de l'Acad. 1703.

Many philosophers have supposed that the elastic property of the air depends on the figure of its corpuscles, which they take to be ramous: some maintain that they are so many minute flocculi, resembling fleeces of wool: others coucive them rolled up like hoops, and curled like wires, or shavings of wood, or coiled like the springs of watches, and endeavouring to expand themselves by virtue of their texture.

But Sir Isaac Newton (Optics, Qu. 31, &c,) explains the matter in a different way: such a texture of parts he thinks by no means sufficient to account for that amazing power of elasticity observed in air, which is capable of dilating itself into above a million of times more space than it occupied before: but, he observes, as it is known that all bodies have an attractive and a repelling power; and as both these are stronger in bodies, the denser, more compact, and solid they are; hence it follows that when, by heat, or any other powerful agent, the attractive force is overcome, and the particles of the body separated so far as to be out of the sphere of attraction; the repelling power, then commencing, makes them recede from each other with a strong force, proportionable to that with which they before cohered; and thus they become permanent air.

And hence, he says, it is, that as the particles of air are grosser, and rise from denser bodies, than those of transient air, or vapour, true air is more ponderous than vapour, and a moist atmosphere lighter than a dry one.

And M. Amontons makes the elasticity of air to arise from the fire it contains; so that by augmenting the degree of heat, the rarefaction will be increased to a far greater degree than by a mere spontaneous dilatation.

The elastic power of the air becomes the second great source of the remarkable effects of this important fluid. By this property it insinuates itself into the pores of bodies, where, by means of this virtue of expanding, which is so easily excited, it must put the particles of those bodies into perpetual vibrations, and maintain a continual motion of dilatation and contraction in all bodies, by the incessant changes in its gravity and density, and consequently its elasticity and expansion.

This reciprocation is observable in several instances, particularly in plants, in which the tracheæ or air-vessels perform the office of lungs; for, as the heat increases or diminishes, the air alternately dilates and contracts, and so by turns compresses the vessels, and eases them again; thus promoting a circulation of their juices. And hence it is found that no vegetation or germination is carried on *in vacuo*.

It is from the same cause too, that ice is burst by the continual action of the air contained in its bubbles. Thus too, glasses and other vessels are frequently cracked, when their contained liquors are frozen; and thus also large blocks of stone, and entire columns of marble, sometimes split in the winter season, from some little bubble of included air acquiring an increased elasticity: and for the same reason it is that so few stones will bear to be heated by a fire, without cracking into many pieces, by the increased expansive force of some air confined within their pores. From the same source arise also all putrefaction and fermentation; neither of which can be carried on *in vacuo*, even in the best-disposed subjects. And even respiration, and animal life itself, are supposed, by many authors, to be conducted, in a great measure, by the same principle of the air. And as we find such great quantities of air generated by the solution of animal and vegetable substances, a good deal must constantly be raised from the dissolution of these elements in the stomach and bowels. In fact, all natural corruption and alteration seem to depend on air; and even metals, particularly gold, only seem to be durable and incorruptible, in so far as they are impervious to air.

Composition, &c, of the air. We have already ob-

served, that for many ages the air we breathe was considered as a simple homogeneous fluid: various exhalations and particles of bodies arising from the earth were indeed observed to mix with it, and on these its different degrees of salinity were supposed to depend; but the aërial fluid itself was never, till within a few years, known to be a compound substance. This point however has been clearly ascertained by the discoveries of modern chemists, particularly those of Priestley, Black, Cavendish, Lavoisier, Fourcroy, &c. From the united testimonies of these discoveries we learn, that atmospheric air is composed of at least two species of air, or elastic fluids, which are called vital air, or oxygen gas, and azotic gas. The former is the great agent in respiration and combustion; and upon the proper proportion of both depends the purity of the atmosphere. The latter possesses contrary qualities, is noxious to animals, and incapable of maintaining combustion. The proportion of these in 100 parts of atmospheric air, is commonly about 26 or 27 parts of oxygen gas, and 74 or 73 parts of azotic gas, by weight; or about 22 parts of the former, and 78 of the latter, in bulk.

These two gases however, though they constitute the principal part of atmospheric air, are not the only ones that enter into its composition; for beside the numerous particles of water and other substances, it contains about 1 part in 100 of carbonic acid gas, and a still smaller quantity of hydrogen gas; and from experiments made upon air brought from the higher regions of the atmosphere, by means of air-balloons, these constituent parts of it were found in nearly the same proportion as at the surface of the earth. For further particulars on this subject, see AZOTE, GAS, OXYGEN, &c.

For the resistance of the air, see RESISTANCE.

AIR-BALLOON. SEE AEROSTATION.

AIR-GUN, in PNEUMATICS, is a machine for propelling bullets with great violence, by the sole means of condensed air.

The first account we meet with of an air-gun, is in the Elements d'Artillerie of David Rivaut, who was preceptor to Louis XIII. of France. He ascribes the invention to Marin, a burgher of Lisieux, who presented one to Henry IV.

To construct a machine of this kind, it is only necessary to take a strong vessel of any sort, into which the air is to be thrown or condensed by means of a syringe, or otherwise, the more the better; then a valve is suddenly opened, which lets the air escape by a small tube in which a bullet is placed, and which is thus violently forced out before the air.

It is evident then that the effect is produced by virtue of the elastic property of the air; the force of which, as has been shown in the last article, is nearly proportional to its condensation; and therefore the greater quantity that can be forced into the engine, the greater will be the effect. Now this effect will be exactly similar to that of a gun charged with powder, and therefore we can easily form a comparison between them: for inflamed gunpowder is nothing more than very condensed elastic air; so that the two forces are exactly similar. It is shown by Mr. Robins, in his New Principles of Gunnery, that the fluid of inflamed gunpowder, has, at the first moment, a force of elasticity equal to about 1000 times that of common air; and I have shown (vol. 3 of my Tracts) that the first force of the inflamed powder is often more

than 2000 times that of the common air. Therefore it is necessary that air should be condensed a 1000 or 2000 times more than in its natural state, to produce the same effect as gunpowder. But then it is to be considered, that the velocities with which equal balls are impelled, are directly proportional to the square roots of the forces; so that if the air in an air-gun be condensed only 10 times, the velocity it will project a ball with, will be, by that rule, $\frac{1}{\sqrt{10}}$ th of that arising from gunpowder; and if the air were condensed 20 times, it would communicate a velocity of $\frac{1}{\sqrt{20}}$ th of that of gunpowder. But in reality the air-gun shoots its ball with a much greater proportion of velocity than as above, and for this reason, namely, that as the reservoir, or magazine of condensed air, is commonly very large in proportion to the tube which contains the ball, the density of the air is very little altered by expanding through that narrow tube, and consequently the ball is urged all the way by nearly the same uniform force as at the first instant; whereas the elastic fluid arising from inflamed gunpowder is but very small in proportion to the tube or barrel of the gun, occupying at first indeed but a very small portion of it next the butt-end; and therefore, by dilating into a comparatively large space, as it urges the ball along the barrel, its elastic force is proportionally more weakened, and it acts always less and less on the ball in the tube. From which cause it happens, that air condensed into a good large machine only 10 times, will shoot its ball with a velocity but little inferior to that given by the gunpowder. And if the valve of communication be suddenly shut again by a spring, after opening it to let some air escape, then the same collection of it serves to impel many balls, one after another.

In all cases in which a considerable force is required, and consequently a great condensation of air, it will be requisite to have the condensing syringe of a small bore, perhaps not more than half an inch in diameter: otherwise the force to produce the compression will become so great, that the operator cannot work the machine: for, as the pressure against every square inch is about 15 pounds, and against every circular inch, or a circle of 1 inch diameter, about 12 pounds, if the syringe be one inch in diameter, when one injection is made, there will be a resistance of 12 pounds against the piston; when 2, of 24 pounds; and when 10 are injected, there will be a force of 120 pounds to overcome; whereas 10 injections act against the half-inch piston, whose area is but $\frac{1}{4}$ of the former, with $\frac{1}{4}$ of the force only, namely, 30 pounds; and 40 injections may be made with such a syringe, as well as 10 with the larger.

Air-guns are of various constructions: an easy and portable one is represented in Plate 2, fig. 1, which is a section lengthways through the axis, to show the inside. It is made of brass, and has two barrels: the inner barrel D A of a small bore, from which the bullets are discharged; and a larger barrel E S C D R, on the outside of it. In the stock of the gun there is a syringe M N P S, whose rod M draws out to take in air; and by pushing it in again, the piston S drives the air before it, through the valve P E, into the cavity between the two barrels. The ball K is put down into its place in the small barrel, with the rammer, as in another gun. There is another valve at S L, which, being opened by the trigger O, permits the air to come behind the ball, so as to drive it out with great force. If this valve be opened and shut sud-

denly, one charge of condensed air may make several discharges of bullets; because only part of the injected air then goes out at a time, and another bullet may be put into the place κ : but if the whole air be discharged on a single bullet, it will impel it more forcibly. This discharge is effected by means of a lock (fig. 2) when fixed to its place as usual in other guns; for the trigger being pulled, the cock will go down, and drive a lever which opens the valve.

Dr. Macbride (Exper. Ess. p. 81) mentions an improvement of the air-gun, made by Dr. Ellis; in which the chamber for containing the condensed air is not in the stock, which renders the machine heavy and unwieldy, but has five or six hollow spheres belonging to it, of about 3 inches diameter, fitted to a screw on the lock of the gun. These spheres are contrived with valves, to confine the air which is forced into their cavities, so that a servant may carry them ready charged with condensed air: and thus the gun of this construction is rendered as light and portable as one of the smallest fowling-pieces.

Fig. 3 represents one made by the late Mr. B. Martin of London, and now by several of the mathematical instrument and gun-makers of the metropolis; which, for simplicity and perfection, perhaps exceeds any other that has been contrived. a is the gun-barrel, of the size and weight of a common fowling-piece, with the lock, stock, and ramrod. Under the lock, at b , is a round steel tube, having a small moveable pin in the inside, which is pushed out when the trigger a is pulled, by the springwork within the lock; to this tube b is screwed a hollow copper ball, perfectly air-tight. This copper ball is fully charged with condensed air by means of a syringe, before it is applied to the tube b . Hence, if a bullet be rammed down in the barrel, the copper ball screwed fast at b , and the trigger a be pulled; the pin in b then will forcibly push open a valve within the copper ball, and let out a portion of the condensed air; which will rush up through the aperture of the lock, and forcibly act against the bullet, driving it to the distance of 60 or 70 yards, or farther. If the air be strongly condensed at every discharge, only a portion of the air escapes from the ball; therefore, by re-cocking the piece, another discharge may be made; and this repeated 15 or 16 times. An additional barrel is sometimes made, and applied for the discharge of shot, instead of the ball above described.

Sometimes the syringe is applied to the end of the barrel c (fig. 4); the lock and trigger shut up in a brass case d ; and the trigger pulled, or the discharge made, by pulling the chain b . In this contrivance there is a round chamber for the condensed air at the end of the spring at e , and it has a valve acting in a similar manner to that of the copper ball. When this instrument is not in use, the brass case d is made to slide off, and the instrument then becomes a walking-stick: from which circumstance, and the barrel being made of cane, or brass, &c, it has been called the *Air-cane*. The head of the cane unscrews and takes off at a , where the extremity of the piston-rod in the barrel is shown. An iron rod is placed in a ring at the end of this, and the air is condensed in the barrel in a manner similar to that of the gun as above; but its force and action is not near so strong as in the gun.

MAGAZINE AIR-GUN. This is an improvement of the common air-gun, made by an ingenious artist, L. Colbe. By his contrivance, ten bullets are so lodged in a cavity, near the place of discharge, that they may be suc-

sively drawn into the barrel, and shot so quickly, as to be nearly of the same use as so many different guns: the only motion required, after the air has been injected, being that of shutting and opening the hammer, and cocking and pulling the trigger. Fig. 5 is a longitudinal section of this gun, as large in every part as the gun itself; and as much of its length is shown as is peculiar to this construction; the rest of it being like the ordinary air-gun. ee is part of the stock; g is the end of the injecting syringe, with its valve ii , opening into the cavity $ffff$ between the barrels. kk is the small or shooting barrel, which receives the bullets, one at a time, from the magazine rr , being a serpentine cavity, in which the bullets $b, b, b, \&c$, are lodged, and closed at the end o ; whence, by one motion of the hammer, they are brought into the barrel at i , and thence are shot out by the opening of the valve v , which lets in the condensed air from the cavity fff into the channel vk , and so along the inner barrel kk , whence the bullet is discharged. $ssss$ mk is the key of a cock, having a hole through it; which hole, in the present situation, makes part of the barrel kk , being just of the same bore: so that the air, which is let in at every opening of the valve v , comes behind this cock, and taking the ball out of it, carries it forward, and so out of the mouth of the piece.

To bring in another bullet to succeed i , which is done in an instant, bring the cylindrical cavity of the key of the cock, which made part of the barrel kk , into the situation ik , so that the part i may be at k ; then turning the gun upside-down, one bullet next the cock will fall into it out of the magazine, but will go no farther into this cylindrical cavity, than the two little pieces ss will permit it; by which means only one bullet at a time will be taken in to the place i , to be discharged again as before.

A more particular description of the several parts may be seen in Desaguliers' Exper. Philos. vol. ii. pa. 399 et seq.

AIR-PUMP, in Pneumatics, is a machine for exhausting the air out of a proper vessel, and thus making what is commonly called a vacuum; though in reality the air in the receiver is only rarefied to a certain degree, so as to take off the ordinary effects of the atmosph α re. By this machine we learn, in some measure, what our earth would be without air; and how much all vital, generative, nutritive, and alterative powers depend upon it.

The principle on which the air-pump is constructed, is the spring or elasticity of the air; as that on which the common, or water pump is formed, is the effect of its gravity: the one gradually exhausting the air from a vessel by means of a piston, with a proper valve, working in a cylindrical barrel or tube; and the other exhausting water in a similar manner.

The invention of this instrument, to which the present age is indebted for so many fine discoveries, is ascribed to Otto Guericke, the celebrated magistrate of Magdeburg, who exhibited his first public experiments with it, before the emperor and the states of Germany, at the breaking up of the imperial diet at Ratisbon, in the year 1654. But it was not till the year 1672 that Guericke published a description of the instrument, with an account of his experiments, in his *Experimenta Nova Magdeburgica de Vacuo Spatio*: though an account of them had been published by Schottus in 1657, in his *Mechanica Hydraulico Pneumatica*, by his consent.

Dr. Hooke and M. Duhamel ascribe the invention of the air-pump to Mr. Boyle. But that great man frankly confesses that Guericke was beforehand with him in the execution. Some attempts, he assures us, he had indeed made on the same foundation, before he knew any thing of what had been done abroad: but the information he afterwards received from the account given by Schottus, enabled him, with the assistance of Dr. Hooke, after two or three unsuccessful trials, to bring his design to maturity. The product of their labours was a new air-pump, much more easy, convenient and manageable, than the German one. And hence, or rather from the great variety of experiments to which this illustrious author applied the machine, it was afterwards called *Machina Boyliana*, and the vacuum produced by it, *Vacuum Boylianum*.

Structure of the Air-Pump. Most of the air-pumps that were first made consisted of only one barrel, or hollow cylinder, of brass, with a valve at the bottom, opening inwards; and a moveable embolus or piston, having likewise a valve opening upwards, and so exactly fitted to the barrel, that when it is drawn up from the bottom, by means of an indented iron rod or rack, and a handle turning a small indented wheel, playing in the teeth of that rod, all the air is drawn up from the cavity of the barrel: there is also a small pipe opening into the bottom of the barrel, by means of which it communicates with any proper vessel to be exhausted of air, which is called a receiver, from its office in receiving the subjects on which experiments are to be made in *vacuo*: the whole being fixed in a convenient frame of wood-work, where the end of the pipe turns up into a horizontal plate, on which the receiver is placed, just over that end of it.

The other parts of the machine, being only accidental circumstances, chiefly respecting convenience, have been diversified and improved from time to time, according to the address and several views of the makers. That of Otto Guericke was very rude and inconvenient, requiring the labour of two strong men, for more than two hours, to extract the air from a glass, which was also placed under water; and which allowed of no change of subjects for experiments.

Mr. Boyle, from time to time, removed several of these inconveniences, and lessened others: but still the working of his pump, which had but one barrel, was laborious, by reason of the pressure of the atmosphere, a great part of which was to be removed at every lift of the piston, when the exhaustion was nearly completed. Various improvements were successively made in the machine, by the philosophers about that time, and soon after, who cultivated this new and important branch of pneumatics; as Papin, Mersenne, Mariotte, and others; but still they laboured under a difficulty of working them, from the circumstance of the single barrel, till Papin, in his further improvements, removed that inconvenience, by the use of a second barrel and piston, contrived to rise, as the other fell, and to fall as that rose; by which means, and the great improvements made by Mr. Hauksbee, the pressure of the atmosphere on the descending piston, always nearly balanced that of the ascending one; so that the winch, which worked them up and down, was easily moved by a very gentle force with one hand: and besides, the exhaustion was hereby made in less than half the time.

Some of the Germans, and others also, made improvements in the air-pump, and contrived it to perform the

counter office of a condenser, in order to examine the properties of the air depending on its condensation.

Mr. Boyle contrived a mercurial gauge or index to the air-pump, which is described in his first and second Physico-Mechanical Continuations, for measuring the degrees of the air's rarefaction in the receiver. This gauge is similar to the barometer, being a long glass tube, having its lower end immersed in an open basin of quicksilver, but its other end, which was open also, communicating with the receiver: which being exhausted, this tube is equally exhausted of air at the same time, and the external air presses the quicksilver up into the tube, to a height proportioned to the degree of exhaustion.

Mr. Vream, an ingenious pneumatic operator, made an improvement in Hauksbee's air-pump, by reducing the alternate up-and-down motion of the hand and winch, to a circular one. In his method, the winch is turned quite round, and yet the pistons are alternately raised and depressed: by which the trouble of shifting the hand backwards and forwards, as well as the loss of time, and the shaking of the pump, are prevented.

The air-pump, thus improved, is represented in plate iii, fig. 1; where *oo* is the receiver to be exhausted, ground truly level at the bottom, set over a hole in the plate, from which descends the bent pipe *hh* to the cistern *dd*, with which the two barrels *aa* communicate, where the pistons are worked by toothed wheel, by turning the handle *bb*; thus the racks *cc*, with the pistons, are worked alternately up and down. *ll* is the gauge tube, immersed in a basin of quicksilver *m* at the bottom, and communicating with the receiver at top; from which however it may be occasionally disengaged, by turning a cock. *nn* is another cock, by turning of which, the air is again let in to the exhausted receiver; into which it is heard to rush with a considerable hissing noise.

Notwithstanding the great excellency of Mr. Hauksbee's air-pump, it was still subject to inconveniences, from which it was in a great measure relieved by some contrivances of Mr. Smeaton, which are described at large in the Philos. Trans. for the year 1752. The principal improvements suggested by Mr. Smeaton, relate to the gauge, the valves of the piston, and the piston going closer down to the bottom of the barrel; for his pump has only one. By the last of these, the air was extracted more perfectly at each stroke. By the second, he remedied an inconvenience arising from the valve hole of the piston being too wide properly to support the bladder valve which covered it: instead of the usual circular orifice, Mr. Smeaton perforated the piston with seven small and equal hexagonal holes, one in the centre, and the other six around, forming together the appearance of a transverse section of a honey-comb; the bars or divisions between which served to support the pressure of the air on the valve. His gauge consists of a bulb of glass, of a pear-like shape, and capable of holding about half a pound of quicksilver: it is open at the lower end, the other terminating in a tube hermetically sealed: and it has annexed to it a scale, divided into parts of about $\frac{1}{10}$ of an inch, and answering to the 1000th part of the whole capacity. During the exhaustion of the receiver, the gauge is suspended in it by a wire; but when the pump has been worked as much as necessary, the gauge is pushed down, till the open end be immersed in a basin of quicksilver placed below. The air is then let into the receiver again, and the quicksilver is driven by it from the basin, up into the gauge, till the

air remaining in it become of the same density as that without; and as the air always takes the highest place, the tube being uppermost, the expansion is determined by the number of divisions occupied by the air at the top. This air-pump is made to act also as a condensing engine, as some German machines had done before, by the very simple operation of turning a cock.

By means of this gauge, Mr. Smeaton judged that his machine was incomparably better than any former one, as it seemed to rarefy the air in the receiver 1000, or even 2000 times, while the best of these only rarefied it about 140 times: and as an implicit confidence was placed in Mr. Smeaton's accuracy, it was generally understood in this light, till the fallacy was accidentally detected in the manner related at large by Mr. Nairne in the Philos. Trans. for the year 1777. This accurate and ingenious artist wanting to make trial of Mr. Smeaton's pear-gauge, executed an air-pump of his improved construction, in the best manner possible; which, in various experiments made with it, appeared, by the pear-gauge, to rarefy the air to an amazing degree indeed, being at times from 4000 to 10000, or 50000, or even 100000 times rarefied. But, on measuring the same expansion by the usual long and short tube gauges, which both accurately agreed together, he found that these never showed a rarefaction of more than 600 times: widely different from the same as measured by the pear or internal gauge, by experiments often repeated. 'Finding' says Mr. Nairne, 'still this disagreement between the pear-gauge and the other gauges, I tried a variety of experiments; but none of them appeared to me satisfactory, till one day in April 1776, when showing an experiment with one of these pumps to the honourable Henry Cavendish, Mr. Smeaton, and several other gentlemen of the Royal Society, the two gauges differed some thousand times from one another, Mr. Cavendish accounted for it in the following manner. "It appeared, he said, from some experiments of his father's, Lord Charles Cavendish; that water, whenever the pressure of the atmosphere on it is diminished to a certain degree, is immediately turned into vapour, and is as immediately turned back again into water on restoring the pressure. This degree of pressure is different according to the heat of the water: when the heat is 72° of Fahrenheit's scale, it turns into vapour as soon as the pressure is no greater than that of three quarters of an inch of quicksilver, or about 1-40th of the usual pressure of the atmosphere; but when the heat is only 41°, the pressure must be reduced to that of a quarter of an inch of quicksilver before the water turns into vapour. It is true, that water exposed to the open air, will evaporate at any heat, and with any pressure of the atmosphere; but that evaporation is entirely owing to the action of the air upon it; whereas the evaporation here spoken of is performed without any assistance from the air. Hence it follows, that when the receiver is exhausted to the above-mentioned degree, the moisture adhering to the different parts of the machine will turn into vapour, and supply the place of the air, which is continually drawn away by the working of the pump; so that the fluid in the pear-gauge, as well as that in the receiver, will consist in a great measure of vapour. Now letting the air into the receiver, all the vapour within the pear-gauge will be reduced to water, and only the real air will remain unconcensed; consequently the pear-gauge shows only how much real air is left in the receiver, and not how much the pressure or

spring of the included fluid is diminished; whereas the common gauges show how much the pressure of the included fluid is diminished, and that equally, whether it consist of air or of vapour." Mr. Cavendish having explained so satisfactorily the cause of the disagreement between the two gauges, Mr. Nairne considered that, if he were to avoid moisture as much as possible, the two gauges should nearly agree. And in fact they were found to do so, each showing a rarefaction of about 600, when all moisture was perfectly cleared away from the pump, and the plate and the edges of the receiver were secured by a cement, instead of setting it upon a soaked leather, as in the usual way. But, by future experiments, Mr. Nairne found that the same excellent machine would not exhaust more than 50 or 60 times, when the receiver was set upon leather soaked in water, the heat of the room being about 57°. And from hence he concludes, that the air-pump of Otto Guericke, and those contrived by Mr. Gratorix and Dr. Hooke, and the improved one by Mr. Papin, both used by Mr. Boyle, as also Hauksbee's, Graviesande's, Muschenbroeck's, and those of all who have used water in the barrels of their pumps, could never have exhausted to more than between 40 and 50, if the heat of the place was about 57°. And though Mr. Smeaton, with his pump, where no water was in the barrel, but where leather soaked in a mixture of water and spirit of wine was used on the pump-plate, to set the receiver upon, may have exhausted all but a thousandth, or even a ten-thousandth part of the common air, according to the testimony of his pear-gauge; yet so much vapour must have arisen from the wet leather, that the contents of the receiver could never be less than a 70th or 80th part of the density of the atmosphere. But when nothing of moisture is used about this machine, it will, when in its greatest perfection, rarely its contents of air about 600 times.

It is evident that, by means of these two gauges, we can ascertain the several quantities of vapour and permanent air which make up the contents of the receiver, after the exhaustion is made as perfect as can be; for the usual external gauge determines the whole contents made up of the vapour and air, while the pear-gauge shows the quantity of real permanent air; consequently the difference is the quantity of vapour.

The principal cause which prevents this pump from exhausting beyond the limit above mentioned, is the weakened elasticity of the air within the receiver, which, decreasing in proportion as the quantity of the air within is diminished, becomes at last incapable of lifting up the valve of communication between the receiver and the barrel; and consequently no more air can then pass from the former to the latter.

Several ingenious persons have used their endeavours to remove this imperfection in the best air-pumps. Among these it seems that one Mr. Haas has succeeded tolerably well; having by means of a contrivance to open the communication valve in the bottom of the barrel, made his machine so correct, that when every thing is in the greatest perfection, it rarefies the contents of the receiver as far as 1000 times, even when measured by the exterior gauge. The description of this machine, and an account of some experiments performed with it, are given by Mr. Cavallo in the Philos. Trans. for the year 1783.

But the imperfections it seems have more recently been removed by an ingenious contrivance of Mr. Cuthbertson, a mathematical instrument maker at Amsterdam, now of

London, whose air-pump has neither cocks nor valves, and is so constructed, that what supplies their place has the advantages of both, without the inconveniences of either. He has also made improvements in the gauges, by means of which he determines the height of the mercury in the tube, by which the degree of exhaustion is indicated, to the hundredth part of an inch. And to obviate the inconvenience of the elastic vapour arising from the wet leather, upon which the receiver is placed, for common experiments, he recommends the use of leather dressed with alum, and soaked in hog's lard, which he found to yield very little of this vapour; but when the utmost degree of exhaustion is required, his advice is, to dry the receiver well, and set it upon the plate without any leather, only smearing its outer edges with hog's lard, or with a mixture of three parts of hog's lard and one of oil. But indeed the use of the leather has long been laid aside by our English instrument-makers, a circumstance which probably had not come to Mr. Cuthbertson's knowledge. An account of this instrument, and of some experiments performed with it, was published at Amsterdam in the year 1787; from which it appears that, by a coincidence of the several gauges, a rarefaction of 1200 times was shown; but when the atmosphere was very dry, the exhaustion has been so complete, that the gauges have shown the air in the receiver to be rarefied above 2400 times.

There are made also by different persons, portable, or small air-pumps, of various constructions, to set upon a table, to perform experiments with. In these, the gauge is varied according to the fancy of the maker, but commonly it consists of a bent glass tube, like a syphon, open only at one end. The gauge is placed under a small receiver communicating, by a pipe, with the principal one leading from the general receiver to the barrels. The close end of the gauge, of 3 or 4 inches long, before the exhaustion, has the quicksilver forced close up to the top by the pressure of the air on the open end; but when the exhaustion is considerably advanced, it begins to descend, and then the difference of the heights of the quicksilver in the two legs, compared with the height in the barometrical tube, determines the degree of exhaustion: so, if the difference between the two be one inch, when the barometer stands at 30, the air is rarefied 30 times; but if the difference be only half an inch, the rarefaction is 60 times, and so on. See Plate III. fig. 2.

The Use of the Air-Pump. In whatever manner or form this machine is made, the use and operation of it are always the same. The handle, or winch, works the rackbar and piston up and down in the barrel; by which means a barrel of the contained air is drawn out at every stroke of the piston, in the following manner: by pushing the piston down to the bottom of the barrel, where the air is prevented from escaping downwards, by its elasticity it opens the valve of the piston, and escapes upwards; then raising the piston up, the external atmosphere shuts down its valve, and a vacuum would be made below it, but for the air in the receiver, pipe, &c, which now raising the valve in the bottom of the barrel, rushes in and fills it again, till the whole air in the receiver and barrel be of one uniform density, but less than it was before the stroke, in proportion as the sum of all the capacities of the receiver, pipe, and barrel together, is to the same sum wanting the barrel. And thus the air in the receiver is diminished at each stroke of the piston, by the quantity or content of

VOL. I.

the barrel or cylinder, and therefore always in the same proportion: so that by thus repeating the operation a number of times, the air is rarefied to any proposed degree, or till it has not elasticity enough to open the valve of the piston or of the barrel, after which the exhaustion cannot be any farther carried on: the gauge, in comparison with the barometer, showing at any time what the degree of exhaustion is, according to the particular nature and construction of it.

But supposing no vapour from moisture, &c, to rise in the receiver, the degree of exhaustion, after any number of strokes of the piston, may be determined by knowing the respective capacities of the barrel and the receiver, including the pipe, &c. For as we have seen above that every stroke diminishes the density in a constant proportion, namely as much as the whole content exceeds that of the cylinder or barrel; consequently the sum of as many diminutions as there are strokes of the piston, will show the whole diminution by all the strokes. So, if the capacity of the barrel be equal to that of the receiver, in which the communication pipe is always to be included; then, the barrel being half the sum of the whole contents, half the air will be drawn out at one stroke; and consequently the remaining half, being dilated through the whole or first capacity, will be of only half the density of the first: in like manner, after the second stroke, the density of the remaining contents will be only half that of the former, that is only $\frac{1}{2}$ of the original density: continuing this operation, it follows that the density of the remaining air will be $\frac{1}{3}$, after 3 strokes of the piston, $\frac{1}{4}$, after 4 strokes, $\frac{1}{5}$, after 5 strokes, and so on, according to the powers of the ratio $\frac{1}{2}$; that is, such power of the ratio as is denoted by the number of the strokes. In like manner, if the barrel be $\frac{1}{2}$ of the whole contents, that is, the receiver double of the barrel, or $\frac{2}{3}$ of the whole contents; then the ratio of diminution of density being $\frac{2}{3}$, the density of the contents, after any number of strokes of the piston, will be denoted by such power of $\frac{2}{3}$ whose exponent is that number; namely, the density will be $\frac{2}{3}$ after one stroke, $(\frac{2}{3})^2$ or $\frac{4}{9}$ after two strokes, $(\frac{2}{3})^3$ or $\frac{8}{27}$ after 3 strokes, and in general it will be $(\frac{2}{3})^n$ after n strokes: the original density of the air being 1. Hence then, universally, if s denote the sum of the contents of the receiver and barrel, and r that of the receiver only without the barrel, and n any number of strokes of the piston; then, the original density of the air being 1, the density after n strokes will be $(\frac{r}{s})^n$ or $\frac{r^n}{s^n}$, namely the n power of the ratio $\frac{r}{s}$. So, for example, if the capacity of the receiver be equal to 4 times that of the barrel; then their sum s is 5, and r is 4; hence the density of the contents after 30 strokes, will be $(\frac{4}{5})^{30}$, or the 30th power of $\frac{4}{5}$, which is $\frac{1}{512}$ nearly; so that the air in the receiver is rarefied 808 times.

See also the Mémoires de l' Acad. Royale des Sciences for the years 1693 and 1705.

From the same formula, namely $(\frac{r}{s})^n = d$ the density, we easily derive a rule for finding the number of strokes of the piston, necessary to rarefy the air any number of times, or to reduce it to a given density d , that of the natural air being 1. For since $(\frac{r}{s})^n = d$, by taking the logarithm of this equation, it is $n \times \log. \frac{r}{s} = \log. d$;

and hence $n = \frac{\log. d}{\log. \frac{r}{s}} = \frac{\log. d}{\log. r - \log. s}$; that is, divide the log.

of the proposed density by the log. of the ratio of the receiver to the sum of the receiver and barrel together, and the quotient will show the number of strokes of the piston requisite to produce the degree of exhaustion required. So, for example, if the receiver be equal to 5 times the barrel, and it be proposed to find how many strokes of the piston will rarefy the air 100 times; then $r = 5$, $s = 6$, $d = \frac{1}{100}$, whose log. is -2 , and $\frac{r}{s} = \frac{5}{6}$, whose log. is -0.7918 ; therefore $\frac{-2}{-0.7918} = 25\frac{1}{4}$ nearly, which is the number of strokes required.

And, farther, the same formula reduced, will give us the proportion between the receiver and barrel, when the air is rarefied to any degree by an assigned number of strokes of the piston. For since $(\frac{r}{s})^n = d$ the density,

therefore, extracting the n root of both sides, it is $\frac{r}{s} = \sqrt[n]{d}$: that is, the n root of the density is equal to the ratio of the receiver to the sum of the receiver and barrel. So, if the density d be $\frac{1}{100}$, and the number of strokes $n = 7$; then the 7th root of $\frac{1}{100}$ is $\frac{1}{2}$; which shows that the receiver is equal to half the receiver and barrel together, or that the capacity of the barrel is just equal to that of the receiver.

Some of the principal effects and phenomena of the air-pump, are the following: That, in the exhausted receiver, heavy and light bodies fall equally swift: so, a guinea and feather fall from the top of a tall receiver to the bottom exactly together. That most animals die in a minute or two: but however, that vipers and frogs, though they swell much, live an hour or two; and after being seemingly quite dead, come to life again in the open air. That snails survive about 10 hours; efts, or slow-worms, two or three days; and leeches five or six. That oysters live for 24 hours. That the heart of an eel taken out of the body, continues to beat for great part of an hour, and that more briskly than in the air. That warm blood, milk, gall, &c, undergo a considerable intumescence and ebullition. That a mouse or other animal may be brought, by degrees, to survive longer in a rarefied air, than naturally it does. That air may retain its usual pressure, after it is become unfit for respiration. That the eggs of silk-worms hatch in vacuo. That vegetation stops. That fire extinguishes; the flame of a candle usually going out in one minute; and a charcoal in about five minutes. That red-hot iron, however, seems not to be affected; and yet sulphur or gunpowder are not lighted by it, but only fused. That a match, after lying seemingly extinct a long time, revives again on re-admitting the air. That a flint and steel strike sparks of fire as copiously, and in all directions, as in air. That magnets, and magnetic needles, act the same as in air. That the smoke of an extinguished luminary gradually settles to the bottom in a darkish body, leaving the upper part of the receiver clear and transparent; and that on inclining the vessel sometimes to one side, and sometimes to another, the fume preserves its surface horizontal, after the nature of other fluids. That heat may be produced by attrition. That camphire will not take fire; and that gunpowder, though some of the grains of a heap of it be kindled by a

burning glass, will not give fire to the contiguous grains. That glow-worms lose their light in proportion as the air is exhausted, and at length become totally obscure; but on re-admitting the air, they presently recover it all. That a bell, on being struck, is not heard to ring, or very faintly. That water freezes. But that a syphon will not run. That electricity appears like the aurora borealis. With multitudes of other curious and important particulars, to be met with in the numerous writings on this machine, namely, besides the Philos. Transactions of most academies and societies, in the writings of Torricelli, Pascal, Mersenne, Guericke, Schottus, Boyle, Hooke, Duhamel, Mariotte, Hauksbee, Hales, Muschenbroeck, Graviesande, Desaguliers, Franklin, Cotes, Helsham, and a great many other authors.

AIR-VESSEL, in Hydraulics, is a vessel of air contained within some water engines, which being compressed, by forcing in a considerable quantity of water, will, by its uniform spring, force it out at the pipe in a constant uninterrupted stream, to a great height.

Air-vessel too, in the improved fire engines, is a metallic cylinder, placed between the two forcing pumps: by the action of the pistons the water is forced into this vessel, through two other pipes, with valves; then the air, previously contained in it, is compressed by the water, in proportion to the quantity admitted, and this, by its spring, forces the water through a pipe by a constant and equal stream; whereas in the common squirting engine, the stream is discontinued between the several strokes.

AJUTAGE, or **ADJUTAGE**, in Hydraulics, part of the apparatus of a jet d'eau, or artificial fountain: being a kind of tube fitted to the aperture or mouth of the cistern, or the pipe; through which the water is to be played in any direction, and in any shape or figure.

It is chiefly the diversity in the ajutage, that makes the different kinds of fountains. So that, by having several ajutages, to be applied occasionally, one fountain is made to have the effect of many.

Mariotte, Graviesande, Desaguliers, and Buat, have written pretty fully on the nature of ajutages, or spouts for jets d'eau, and especially the former. He affirms, from experiment, that an even polished round hole, made in the thin end of a pipe, gives a higher jet than either a cylindrical or a conical ajutage; but that, of these two latter however, the conical is better than the cylindrical figure. See his Traité du Mouvement des Eaux, part 4.

The quantity of water discharged by ajutages of equal area, but of different figures, is the same. And for like figures, but of different sizes, the quantity discharged, is directly proportional to the area of the ajutage, or to the square of its diameter, or of any side or other linear dimension: so, an ajutage of a double diameter, or side, will discharge 4 times the quantity of water; of a triple diameter, 9 times the quantity; and so on; supposing them at an equal depth below the surface or head of water. But if the ajutage be at different depths below the head, then the celerity with which the water issues, and consequently the quantity of it run out in any given time, is directly proportional to the square root of the altitude of the head, or depth of the hole: so at 4 times the depth, the celerity and quantity is double; at 9 times the depth, triple; and so on.

It has been found that jets do not rise quite so high as the head of water; owing chiefly to the resistance of the air against it, and the pressure of the upper parts of the

jet upon the lower: and for this reason it is, that if the direction of the ajutage be turned a very little from the perpendicular, it is found to spout rather higher, than when the jet is exactly upright.

It is found by experiment too, that the jet is higher or lower, according to the size of the ajutage; that a circular hole of about an inch and a quarter in diameter, jets highest; and that the nearer that size, the better. Experience also shows, that the pipe leading to the ajutage, should be much larger than it; and if the pipe be a long one, that it should be wider the farther it is from the ajutage.

For the other circumstances relating to jets and the issuing of water under various circumstances, see EXHAUSTION, FLUX, FOUNTAIN, JET D'EAU, &c, to which they more properly belong.

ALBATEGNI, an Arabic prince of Batan in Mesopotamia, who was a celebrated astronomer, about the year of Christ 880, as appears by his observations. He is also called Muhammed ben Geber Albategni, Mahomet the son of Geber, and Muhamedes Aractensis. He made astronomical observations at Antioch, and at Racab or Aracta, a town of Chaldea, which some authors call a town of Syria or of Mesopotamia. He is highly spoken of by Dr. Halley, as a vir admirandi acuminis, ac in administrandis observationibus exercitissimus.

Finding that the tables of Ptolemy were imperfect, he computed new ones, which were long used as the best among the Arabs: these were adapted to the meridian of Aracta or Racab. Albategni composed in Arabic a work under the title of The Science of the Stars, comprising all parts of astronomy, according to his own observations and those of Ptolemy. This work, translated into Latin by Plato of Tibur, was published at Nuremberg in 1537, with some additions and demonstrations of Regiomontanus; and the same was reprinted at Bologna in 1645, with this author's notes. Dr. Halley detected many faults in these editions: Philos. Trans. for 1693, N° 204.

In this work, Albategni gives the motion of the sun's apogee since Ptolemy's time, as well as the motion of the stars, which he makes 1 degree in 70 years. He made the longitude of the first star of Aries to be 189° 2'; and the obliquity of the ecliptic 23° 35'. And upon Albategni's observations were founded the Alphonsine tables of the moon's motions; as is observed by Nic. Muler, in the Tab. Frisicæ, pa. 248.

ALBERTUS MAGNUS, a very learned man in the 13th century, who, among a multitude of books, wrote several on the various mathematical sciences, as Arithmetic, Geometry, Perspective or Optics, Music, Astrology and Astronomy, particularly under the titles, de sphæra, de astris, de astronomia, item speculum astronomicum.

Albertus Magnus was born at Lawingen on the Danube, in Suabia, in 1205, or according to some in 1193; and he died at a great age, at Cologn, November 15, 1280. Vossius and other authors speak of him as a great genius, and deeply skilled in all the learning of the age. His writings were so numerous, that they make 21 volumes in folio, in the Lyons edition of 1615. He has passed also for the author of some writings relating to midwifery, &c, under the title of De natura rerum, and De secretis mulierum, in which there are many phrases and expressions unavoidable on such a subject, which gave great offence, and raised a clamour against him as the supposed author,

and inconsistent with his character, being a Dominican friar, and sometime bishop of Ratisbon; which dignity however he soon resigned, through his love for solitude, to enter again into the monastic life. But the advocates of Albert assert, that he was not the author of either of these two works. It must be acknowledged however, that there are, in his Comment on the Master of Sentences, some questions concerning the practice of conjugal duty, in which he has used some words rather too gross for chaste and delicate ears: but they allege what he himself used to say in his own vindication, that he came to the knowledge of so many monstrous things at confession, that it was impossible to avoid touching upon such questions. Albert was certainly a man of a most curious and inquisitive turn of mind, which gave rise to other accusations against him; such as, that he laboured to find out the philosopher's stone; that he was a magician; and that he made a machine in the shape of a man, which was an oracle to him, and explained all the difficulties he proposed: the common cant accusations of those times of ignorance and superstition. But having great knowledge in the mathematics and mechanics, by his skill in these sciences he probably formed a head, with springs capable of articulate sounds; like the machines of Boetius and others.

John Matthæus de Luna, in his treatise De Rerum Inventoribus, has attributed the invention of fire-arms to Albert; but in this he is refuted by Naude, in his Apologie des grands hommes.

ALBUMAZAR, otherwise called ABUASSAR, and JAPHAR, was a celebrated Arabian philosopher and astrologer, of the 9th or 10th century, or according to some authors much earlier. Blancanus, Voissius, &c, speak of him as one of the most learned astronomers of his time, or astrologer, which was then the same thing. He wrote a work De Magnis Conjunctionibus Annorum Revolutionibus, ac eorum Perfectionibus, printed at Venice in 1515, at the expense of Melchior Sessa, a work chiefly astrological.

He wrote also Introductio in Astronomiam, printed in the year 1489. And it is reported that he observed a comet in his time, above the orb of Venus.

ALDEBARAN, the Arabian name of a fixed star, of the first magnitude, just in the eye of the sign or constellation Taurus, or the bull, and hence it is popularly called the bull's eye. For the beginning of the year 1800, its

Right Ascension is.....	66° 6' 51" 10
Annual variation in AR.....	0 0 51:31
Declination	16° 5' 52":00 N.
And Annual variat. in Decl.	0 0 8:30

ALDERAIMIN, a star of the third magnitude in the right shoulder of the constellation Cepheus.

ALDHAFERA, or Aldaphira, in the Arabian Astronomy, denotes a fixed star of the third magnitude, in the man of the sign or constellation Leo, the lion.

ALEMBERT (John le Rond d'). See DALEMBERT.

ALFECCA, or Alfeta, a name given to the star commonly called Lucida Coronæ.

ALFRAGAN, ALFERGANI, or FARGANI, a celebrated Arabic astronomer, who flourished about the year 800. He was so called from the place of his nativity, Fergan, in Sogdiana, now called Maracanda, or Samarcand, anciently a part of Bactria. He is also called Ahmed (or Muhammed) ben-Cothair, or Katir. He wrote

the Elements of Astronomy, in 30 chapters or sections. In this work the author chiefly follows Ptolemy, using the same hypotheses, and the same terms, and frequently citing him.

There are three Latin translations of Alfragan's work. The first was made in the 12th century, by Joannes Hispanensis; and was published at Ferrara in 1493, and at Nuremberg in 1537, with a preface by Melancthon. The second was by James Christman, from the Hebrew version of James Antoli, and appeared at Frankfort in 1590. Christman added to the first chapter of the work an ample commentary, in which he compares together the calendars of the Romans, the Egyptians, the Arabians, the Persians, the Syrians, and the Hebrews, and shows the correspondence of their years.

The third and best translation was made by Golius, professor of mathematics and Oriental languages at Leyden: this work, which came out in 1669, after the death of Golius, is accompanied with the Arabic text, and many learned notes upon the first nine chapters; for this author was not spared to carry them farther.

ALGAROTI, commonly called Count Algaroti, a celebrated Italian of the last century, well skilled in Architecture and the Newtonian philosophy, &c. Algaroti was born at Padua, but in what year has not been mentioned. Led by curiosity, as well as a desire of improvement, he travelled early into foreign countries; and was very young when he arrived in France in 1736. It was here that he composed his Newtonian Philosophy for the Ladies, as Fontenelle had done his Cartesian Astronomy, in the work entitled The Plurality of Worlds. He was much noticed by the king of Prussia, who conferred on him many marks of his esteem. He died at Pisa the 23d of May, 1764, and gave orders for his own mausoleum, with this inscription upon it; *Hic jacet Algarotus, sed non omnis.* He was esteemed to be well skilled in painting, sculpture, and architecture. His works, which are numerous, and on a variety of subjects, abound with vivacity, elegance, and wit: a collection of them has lately been made, and printed at Leghorn; but that for which he is chiefly entitled to a place in this work is his Newtonian Philosophy for the Ladies, a sprightly, ingenious, and popular work.

ALGEBRA is usually understood to be a general method of resolving mathematical problems by means of equations. Or, it is a method of performing the calculations of all kinds of quantities by means of general signs or characters. At first, numbers and things were expressed by their names at full length; but afterwards these were abridged, and the initials of the words used instead of them; and, as the art advanced farther, the letters of the alphabet came to be employed as general representations of all kinds of quantities. Other marks were also gradually introduced, to express all sorts of operations and combinations; so as to entitle it to different appellations—as, universal arithmetic, and literal arithmetic, and the arithmetic of signs.

The etymology of the name, Algebra, is given in various ways. It is, however, pretty generally considered, that the word is Arabian, and that from those people we had the name, as well as the art itself, as is testified by Lucas de Burgo, the first European author on this art, whose treatise was printed, and who also refers to former authors and masters, from whose writings he had learned

it. The Arabic name he gives it, is Algehra e Almucabala, which is explained to signify the art of restitution and comparison, or opposition and restoration, or resolution and equation, all which agree well enough with the nature of this art. Some, however, derive it from various other Arabic words; as from Geber, a celebrated philosopher, chemist, and mathematician, to whom also they ascribe the invention of this science: and some derive it from the word Geber, which, with the particle *al*, makes Algeber, which is purely Arabic, and signifies the reduction of broken numbers or fractions to integers.

But Peter Ramus, in the beginning of his algebra, says, “the name algebra is Syriac, signifying the art and doctrine of an excellent man. For Geber, in Syriac, is a name applied to men, and is sometimes a term of honour, as master or doctor among us. That there was a certain learned mathematician, who sent his algebra, written in the Syriac language, to Alexander the Great, and he named it Almucabala, that is, the book of dark or mysterious things, which others would rather call the doctrine of algebra. And to this day the same book is in great estimation among the learned in the oriental nations, and by the Indians who cultivate this art it is called aljabra, and alboret; though the name of the author himself is not known.” But Ramus gives no authority for this singular paragraph. It has, however, on various occasions been distinguished by other names. Lucas Pacioli, or de Burgo, in Italy, called it l'Arte Magiore; ditte dal vulgo la Regola de la Cosa over Algehra e Almucabala; calling it l'Arte Magiore, or the greater art, to distinguish it from common arithmetic, which is called l'Arte Minore, or the lesser art. It seems too that it had been long and commonly known in his country by the name Regola de la Cosa, or Rule of the Thing; whence came our rule of coss, cosic numbers, and such-like terms. Some of his countrymen followed his denomination of the art: but other Italian and Latin writers called it Regula rci et census, the rule of the thing and the product, or the root and the square, as the unknown quantity in their equations commonly ascended no higher than the square or second power. From this Italian word *census*, pronounced *chensus*, came the barbarous word *zensus*, used by the Germans and others, for quadratics; with the several zenzic or square roots. And hence $\sqrt{2}$, $\sqrt{3}$, \sqrt{c} , which are derived from the letters *r*, *z*, *c*, the initials of *res*, *zensus*, *cubus*, or root, square, cube, came to be the signs or characters of these words: like as $\sqrt{2}$ and $\sqrt{3}$, derived from the letters *R*, *r*, became the signs of radicality.

Later authors, and other nations, used some the one of those names, and some another. It was also called specious arithmetic by Vieta, on account of the species, or letters of the alphabet, which he brought into general use; and by Newton it was called universal arithmetic, from the manner in which it performs all arithmetical operations by general symbols, or indeterminate quantities.

Some authors define algebra to be the art of resolving mathematical problems: but this is the idea of analysis, or the analytic art in general, rather than of algebra, which is only one particular species of it. Indeed, algebra properly consists of two parts: first, the method of calculating magnitudes or quantities, as represented by letters or other characters; and secondly, the manner

of applying these calculations in the solution of problems.

In algebra, as applied to the resolution of problems, the first business is to translate the problem out of the common, into the algebraic language, by expressing all the conditions and quantities, both known and unknown, by their proper characters, arranged in an equation, or several equations if necessary, and treating the unknown quantity, whether it be number, or line, or any other thing, in the same way as if it were a known one: this forms the composition. Then the resolution, or analytic part, is the disentangling the unknown quantity from the several others with which it is connected, so as to retain it alone on one side of the equation, while all the other, or known quantities, are collected on the other side, and so giving the value of the unknown one. And as this disentangling of the quantity sought, is performed by the converse of the operations by which it is connected with the others, taking them always backwards in the contrary order, it hence becomes a species of the analytic art, and is called the modern analysis, in contradistinction to the ancient analysis, which chiefly respected geometry, and its applications.

There have arisen great controversies and sharp disputes among authors, concerning the history of the progress and improvements of algebra; arising partly from the partiality and prejudices which are natural to all nations, and partly from the want of a closer examination of the works of the older authors on this subject. From these causes it has happened, that the improvements made by the writers of one nation, have been ascribed to those of another; and the discoveries of an earlier author, to some one of much later date. Add to this also, that the peculiar methods of many authors have been described so little in detail, that our information derived from such histories is but very imperfect, and amounting only to some general and vague ideas of the true state of the arts. To remedy this inconvenience therefore, and to reform this article, I have taken the pains carefully to read over in succession all the older authors on the subject, which I have been able to meet with, and to write down distinctly a particular account and description of their several compositions, as to their contents, notation, improvements, and peculiarities; from the comparison of all which, I have acquired an idea more precise and accurate than it was possible to obtain from other histories, and in a great many instances very different from them. The full detail of these descriptions would employ a volume of itself, and would be far too extensive for this place: I must therefore limit this article to a very brief abridgment of my notes, remarking only the most material circumstances in each author; from which a general idea of the chain of improvements may be perceived, from the first rude beginnings, down to the more perfect state; from which it will appear that the discoveries and improvements made by any one single author, are scarcely ever either very great or numerous; but that, on the contrary, the improvements are almost always very slow and gradual, from former writers, successively made, not by great leaps, and after long intervals of time, but by gradations which, viewed in succession, become almost imperceptible.

Or DIOPHANTUS'S ALGEBRA. As to the origin of the analytic art, of which algebra is a species, it is doubtless as old as any science in the world, being the natural

method by which the mind investigates truths, causes, and theories, from their observed effects and properties. Accordingly, traces of it are observable in the works of the earliest philosophers and mathematicians, the subject of whose enquiries most of any require the aid of such an art. And this process constituted their analytics. Of that part of analytics, however, which is properly called algebra, the oldest treatise which has come down to us, is that of Diophantus of Alexandria, who flourished about the year 150 after Christ, and who wrote, in the Greek language, 13 books of algebra or arithmetic, as mentioned by himself at the end of his address to one Dionysius, though only 6 of them have hitherto been printed; and an imperfect book on multangular numbers, namely, in a Latin translation only, by Xilander, in the year 1573, and afterwards in 1621 and 1670 in Greek and Latin by Gaspar Bachet. These books, however, do not contain a treatise on the elementary parts of algebra, but only collections of difficult questions relating to square and cube numbers, and other curious properties of numbers, with their solutions. And Diophantus only prefaces the books by an address to Dionysius, for whose use it was probably written, in which he just mentions certain precognita, as it were to prepare him for the problems themselves. In these remarks he shows the names and generation of the powers, the square, cube, 4th, 5th, 6th, &c, which he calls dynamis, cubus, dynamodynamis, dynamocubus, cubocubus, according to the sum or addition of the indices of the powers; and he marks these powers with the initials thus $\delta\bar{\nu}$, $x\bar{\nu}$, $\delta\delta\bar{\nu}$, $\delta x\bar{\nu}$, $xx\bar{\nu}$, &c: the unknown quantity he calls simply $\alpha\gamma\beta\psi\omega\zeta$, numerus, the number; and in the solutions he commonly marks it by the final thus ζ ; also he denotes the monades, or indefinite unit, by $\mu\bar{\nu}$. Diophantus then remarks on the multiplication and division of simple species together, showing what powers or species they produce; declares that minus ($\lambda\epsilon\nu\psi\zeta$) multiplied by minus produces plus ($\sigma\tau\alpha\zeta\xi\psi$); but that minus multiplied by plus, produces minus; and that the mark used for minus is ψ , namely the ψ inverted and curtailed; but he uses no mark for plus, but a word or conjunction copulative.

As to the operations, viz, of addition, subtraction, multiplication, and division of compound species, or those connected by plus and minus, Diophantus does not teach, but supposes his reader to know them. He then remarks on the preparation or simplifying the equations that are derived from the questions, which we call reduction of equations, by collecting like quantities together, adding quantities that are minus, and subtracting such as are plus, called by the moderns transposition, so as to bring the equation to simple terms, and then depressing it to a lower degree by equal division, when the powers of the unknown quantity are in every term: which preparation, or reduction of the complex equation, being now made, or reduced to what we call a final equation, Diophantus goes no farther, but barely says what the root or *res ignota* is, without giving any rules for finding it, or for the resolution of equations; thereby intimating that such rules were to be found in some other work, done either by himself or others.

Of the body of the work, lib. 1 contains 43 questions, concerning one, two, three, or four unknown numbers, having certain relations to each other, viz, concerning

their sums, differences, ratios, products, squares, sums and differences of squares, &c, &c; but none of them concerning either square or cubic numbers. Lib. 2 contains 36 questions. The first 5 questions are concerning two numbers, though only one condition is given in each question; but he supplies another by assuming the numbers in a given ratio, viz, as 2 to 1. The 6th and 7th contain each two conditions: then in the 8th question he first comes to treat of square numbers, which is this, to divide a given square number into two other squares; and the 9th is the same, but performed in a different way: the rest, to the end, are almost all about one, two, or three squares. Lib. 3 contains 24 questions concerning squares, chiefly including three or four numbers. Lib. 4 begins with cubes; the first of which is this, to divide a given number into two cubes whose sides shall have a given sum: here he has occasion to cube the two binomials $5+n$ and $5-n$; the manner of doing which shows that he was acquainted with the composition of the cube of a binomial; and many other places manifest the same thing. Only part of the questions in this book are concerning cubes; the rest are relating to squares. Two or three questions in this book have general solutions, and the theorems deduced are general, and for any numbers indefinitely; but all the other questions, in all the four books, are employed in finding only particular numbers. Lib. 5 is also concerning square and cube numbers, but of a more difficult kind, beginning with some that relate to numbers in geometrical progression. Lib. 6 contains 26 propositions, concerning right-angled triangles; such as to make their sides, areas, perimeters, &c, &c, squares or cubes, or rational numbers, &c. In some parts of this book it appears, that Diophantus was acquainted with the composition of the 4th power of the binomial root, as he sets down all the terms of it; and, from his great skill in such matters, it seems probable that he was acquainted with the composition of other higher powers, and with other parts of algebra, besides what are here treated of. At the end is part of a book, in 10 propositions, concerning arithmetical progressions, and multangular or polygonal numbers. Diophantus once mentions a compound quadratic equation; but the resolution of his questions is by simple equations, and by means of only one unknown letter or character, which he chooses or assumes so ingeniously, that all the other unknown quantities in the question are easily expressed by it, and the final equation reduced to the simplest form which it seems the question can admit of. Sometimes he substitutes for a number sought immediately, and then expresses the other numbers or conditions by it: at other times he substitutes for the sum or difference, &c, and thence derives the rest, so as always to obtain the expressions in the simplest form. Thus, if the sum of two numbers be given, he substitutes for their difference; and if the difference be given, he substitutes for their sum: in both cases he has the two numbers easily expressed by adding and subtracting the half sum and half difference; and so in other cases he uses other similar ingenious notations. In short, the chief excellence in this collection of questions, which seems to be only a set of exercises to some rules which had been given elsewhere, is the neat mode of substitution or notation; which being once made, the reduction to the final equation is easy and evident; and there he leaves the solution, only mentioning that the root or *αριθμός* is so much. On the whole, this work is treated in a very

able and masterly manner, manifesting the utmost address and knowledge in the solutions, and inducing a persuasion that the author was deeply skilled in the science of algebra, to some of the most abstruse parts of which these questions or exercises relate. However, as he contrives his assumptions and notations so as to reduce all his conditions to a simple equation, or at least a simple quadratic, it does not appear what his knowledge was in the resolution of compound or affected equations.

But though Diophantus was the first author on algebra that we now know of, it was not from him, but from the Moors or Arabians that we received the knowledge of algebra in Europe, as well as that of most other sciences. And it is matter of dispute who were the first inventors of it; some ascribing the invention to the Greeks, while others say that the Arabians had it from the Persians, and these from the Indians, as well as the arithmetical method of computing by ten characters, or digits; but the Arabians themselves say it was invented among them by one Mahomet ben Musa, 'or son of Moses, who it seems flourished about the 8th or 9th century.' It is more probable, however, that Mahomet was not the inventor, but only a person well skilled in the art; and it is further probable, that the Arabians drew their first knowledge of it, either from the Indians, or from Diophantus and other Greek writers, as they did that of geometry and other sciences, which they improved and translated into their own language; and from them it was that Europe received these sciences, before the Greek authors were known to us, after the Moors settled in Spain, and after the Europeans began to hold communication with them, and began to travel among them to learn the sciences. And according to the testimony of Abulpharagius, in the year 969, the arithmetic of Diophantus had been translated into Arabic by Mahomet ben-yahya Buziani. But whoever were the inventors and first cultivators of algebra, it is certain that the Europeans first received the knowledge, as well as the name, from the Arabians or Moors, in consequence of the close intercourse which subsisted between them for several centuries. And it appears that the art was pretty generally known, and much cultivated, at least in Italy, if not in Spain, as well as other parts of Europe also, long before the invention of printing, as many writings on the art are still extant in the libraries of manuscripts; and the first authors, presently after the invention of printing, speak of many former writers on this subject, from whom they learned the art.

OF THE INDIAN ALGEBRA. Some notices have lately been obtained of the science of algebra among the Indians; and it is very probable that, through the intercourse of learned Englishmen with that country, we shall receive still more considerable information on that head.

There has long existed cause to suspect that the principles of this art came to Europe through the Arabians and Moors, as well as the Indian numeration and arithmetic; and every extension of our concerns among them, serves further to increase the probability of that opinion. For more than a century past, evidence has been received in Europe, at various times, of the existence of very learned works on astronomy among the Indians. Such notices were first imported by certain learned Frenchmen, and communicated through the Memoirs of the Academy; whence a very ingenious and learned account of such works was given in the *Astronomie Indienne* of the unfortunate M. Bailly. Since then, many other valuable com-

munications have been made by several of our own learned countrymen, belonging to the Bengal Society, and other persons curious in the sciences; as sir William Jones, Samuel Davis, esq., Edward Strachey, esq., and many others. Hence the strongest evidence has been obtained, that, at a period several thousand years (at least three or four) before the Christian era, the Indians must have possessed very correct astronomical observations and rules of calculation; rules that require a considerable knowledge of geometry and of trigonometry, both plane and spherical; and even accompanied with regular tables of sines and versed sines: at a time when all Europe was in a state of gross barbarity, if it was at all inhabited. See a valuable paper in the 2d volume of the Asiatic Researches, by Samuel Davis, Esq. on the Astronomical Computations of the Hindus; also two learned dissertations on the Indian Astronomy and Trigonometry, by Professor Playfair, in the Edinburgh Philosophical Transactions, vols. ii. and iv.

What we have now, however, particularly to attend to, is the algebra of that country. It has long been thought that a people, possessing so much knowledge of many other branches of mathematical science, could not well be unacquainted with algebra; and we have now received incontrovertible proofs of their very critical skill in that branch. Several specimens of such works have been seen in that country, both in the native language and in Persian translations. Some of the latter are also now in the hands of S. Davis, esq. of Portman Square, one of the directors of the East-India Company, with a partial translation into English; and similar translations of some others have been sent to England by Mr. Edward Strachey, before mentioned. And as I have been favoured with the perusal of these, I am enabled to give some account of them.

The first of these communications, by Mr. Strachey, of the Bengal civil establishment, is a printed account of some observations on the originality, extent, and importance, of the mathematical science of the Hindoos; with extracts from Persian translations of the Lilawati or Leelawuttee, and the Beej Gunnit; or the Bija Ganita, as it is written by Mr. Davis. These two works, Mr. Strachey informs us, were both written by Bhasker Acharij, a famous Hindoo mathematician and astronomer, who lived about the beginning of the 13th century of the Christian era; the latter of these two treatises being on algebra, with some of its applications; and the former on arithmetic, and algebra, and mensuration or practical geometry. The Beeja or Bija Ganita was translated into Persian in 1634, by Utta Ulla Ruschedee, at Agra or Dehli probably; and the Leelawuttee in 1587, by the celebrated Fyzee.

It is well known, Mr. Strachey says, that the only Persian science is Arabian, and that the Arabs had much of their mathematical knowledge from the Greeks; it is certain, however, that they had their arithmetic from the Indians, and most likely their algebra was drawn from the same source; but the time, and other circumstances respecting the introduction of these sciences among the Arabs, is unknown. It appears, however, that the first account of any Indian mathematical science among the Arabs, was of their astronomy, which was known in the reign of Al Mamoon. In later times, many Mahommedans have had access to the Hindoo books; accounts of several are in the Ayeen Ackbery, and in D'Herbelot.

Abul Fuzl gives a list of Sanscrit books, which were translated into Persian in Akbar's time; among which the Leelawuttee is the only mathematical work.

From a comparison of the algebra of the Arabians and Greeks, and that of the modern Europeans, with the Persian translations of the Beja Ganita and Leelawati, it would probably appear, that the algebra of the Arabs is quite different from that of Diophantus, and not taken the one from the other; that if the Arabs did learn from the Indians, as is most probable, they did not borrow largely from them; that the Persian translations of the Beej Gunnit and Leelawuttee, contain principles, which are sufficient for the solution of any propositions in the Arabian, or in the Diophantine algebra; that these translations contain propositions, which are not to be solved on any principles that could be supplied by the Arabian or the Diophantine algebra; and that the Hindoos were farther advanced in some branches of this science than the modern Europeans, with all their improvements, till the middle of the eighteenth century.

These premises are exemplified by several extracts from the Lilawati and the Beja Ganita, too long to be repeated here, but are to be seen in my Tracts, vol. 2, p. 154, &c; where we trace many instances of the Hindoos' knowledge in geometry, and in mensuration, as well as in the various parts of algebra, as far as compound quadratic equations inclusively, and that after a more perfect manner, in some respects, than our own practice.

On Indeterminate Problems of the Second Degree, Diophantus, and the Bija Ganita.

The 16th question of the 6th book of Diophantus, is as follows:—

“ Having two numbers given, if one of these drawn into a certain square, and the other subtracted from the product, make a square; it is required to find another square, greater than the former, which shall do the same thing. For instance, given the two numbers 3 and 11, and a certain square 25, which drawn into 3, and 11 taken from the product, leaves the square of 8; to find another square greater than 25 having the same property. Put its side $1n + 5$, then its square is $1q + 10n + 25$; triple of this diminished by 11 leaves $3q + 30n + 64$ equal a square; let its side be $2n - 8$, which gives $n = 62$; then $62 + 5 = 67$ is the side, and 4489 the square sought.”

In the Bija Ganita this problem is solved very generally and scientifically, by the assistance of another, which was unknown in Europe till the middle of the 17th century; and first applied to questions of this nature by Euler, in the middle of the 18th century.—With the affirmative sign, the Bija Ganita rule for finding new values of $ax^2 + b = y^2$, is this: Suppose $ag^2 + b = h^2$ a particular case: find m and n such that $an^2 + 1 = m^2$; then is $x = mg + nh$, and $y = mh + ang$.

General methods, according to the Hindus, for the solution of indeterminate problems of the first and second degrees, are found in the 4th and 5th chapters of the Bija Ganita, which differ much from Diophantus's work. It contains, a great deal of knowledge and skill, which the Greeks had not; such as, the use of an indefinite number of unknown quantities, and the use of arbitrary marks to express them; a good arithmetic of surds; a perfect theory of indeterminate problems of the first degree; a very extensive and general knowledge of those of the second degree; a perfect acquaintance with quadratic equations, &c. The arrangement and manner of the two works

are as different as their substance: the one constitutes a regular body of science; the other does not: the Bija Ganita is quite connected and well digested, and abounds in general rules, which suppose great learning; the rules are illustrated by examples, and the solutions are performed with skill. Diophantus, though not entirely without method, gives very few general propositions, being chiefly remarkable for the dexterity and ingenuity with which he makes assumptions for the simple solution of his questions. The former teaches algebra as a science, by treating it systematically; the latter sharpens the wit, by solving a variety of abstruse and complicated problems in an ingenious manner. The author of the Bija Ganita goes deeper into his subject, treats it more abstractedly, and more methodically; though not more acutely than Diophantus. The former has every characteristic of an assiduous and learned compiler; the latter of a man of genius in the infancy of science.

Besides the foregoing remarks, derived chiefly from the printed notices of Mr. Strachey, I have lately been favoured with communications of several other curious particulars relating to the same two books, by S. Davis, esq. The late Mr. Reuben Burrow collected, in India, many oriental manuscripts on the mathematical sciences, both in the Sanscrit and the Persian languages, the latter being translations only of the former: most of these he bequeathed by will to one of his sons there, but with an injunction not to be delivered to him till he should have learned those languages and the sciences. But one or two of these Burrow left to his friend Mr. Dalby, mathematical professor at the Royal Military College, Farnham. These are now in Mr. Dalby's possession, being the Persian translations of the Bija Ganita and Lilawati, with an attempt at an English translation of some parts of them by Mr. Burrow; but these attempts being mostly interlineations written with a black-lead pencil, are in danger of being obliterated. Mr. Strachey also, lately arrived from India, has an entire English translation of the Bija, of which he has favoured me with the perusal, and besides communicated by letter many descriptive remarks of those works, from all which sources I have collected the following curious particulars, till such time as he may be pleased to give the whole work to the public.

The first work is called the Beej, or the Beej Gunnit (as they are pronounced, but written Bija Ganita), and seems to have been translated into Persian about the year 1634. The Persian introduction calls it "Beej Gunnit, the author Blasker Acharya, author of the Lilawati." It is there also said, that "this excellent method of computation was translated from the Hindu into Persian, and is called the Book of Composition and Resolution;" and "that it is not written in any book, Persian or Arabic." The two words here translated "composition and resolution," are elsewhere simply called "algebra." The two Persian words for "Beej Gunnit," are totally different from them; so that the Persians and Arabians have adopted the meaning, not the pronunciation, of the Sanscrit. Part of the ms. is a commentary on the original Hindoo work, by the Persian translator.

The work consists of five parts. It commences with explaining affirmatives and negatives, which he characterises by two terms denoting *existing* and *non-existing*, also *property* and *debt*. Then follow the first rules, as with us. Next, surds are given at great length; and there seems here a general method of finding the number of surds in

any powers raised from multinomial surd roots, something like our method of finding the number of combinations. Next follow questions about squares; such as (using our own notation), finding $67x^2+1$, and $61x^2+1$, and $13x^2-1$, &c, squares; also a general way or method to make expressions of this kind ax^2+b squares.

Then questions are treated producing simple equations; with the application to some questions about triangles. Then more questions about squares; as, to find $x \pm y$ and xy both squares; also x^3+y^3 and x^2+y^2 both squares.

Next, some questions producing quadratics. Something is also said of a cubic; but it seems to hint that it cannot be solved generally: a straight ruler is mentioned, which it is suspected may allude to some mechanical method of solution, for there is an omission in the translation. Then more about squares; such as, to find $x-y$ both $7x^2+8y^2$ squares; $7x^2-8y^2+1$ both x^2+y^2 squares; x^2+y^2 squares; $7x^2-8y^2+1$ squares; $x+y$ both $x-y$ squares; $x+y+2$ squares; x^2-y^2+1 squares; $x-y$ a square; $x+y+2$ squares; x^2+y^2+1 squares; x^2-y^2 a cube in whole numbers; $\frac{x^2-a}{b}$ a whole number, &c, &c.

Lastly, more indeterminate questions. In short, a great part is about indeterminate, and what we call questions of the Diophantine kind, yet without any one being the very same as in that author; which alone seems to show a different origin; besides, they are mostly treated in a very different way; and several of them are not easy.

There are three or four questions about right-angled triangles, done algebraically; and here one might have expected to have found Eucl. 47, I, quoted; but, instead of that, a reference is made to the "figure of wedding chair." But from these, and many other parts of their writings, we perceive that they were possessed of, not this property only, but most others the same as in our geometry; and here it was probably that Pythagoras acquired his mathematical knowledge, which he carried back with him, and taught to his countrymen. The results of the operations by the cipher 0, are the same as we make them: the quotient $\frac{a}{0}$ Burrow at first translated "infinite," but afterwards crossed it with his pencil, and substituted "cannot be comprehended;" probably it means *unbounded*, or *in訾gnable*.

Respecting this notation in this ms. it appears that unknown quantities are represented by letters or characters, which they call "colours." Thus, when only one unknown is used, it is denoted by a character called "Majool;" when two unknowns enter into the computation, the second is "Aswad" (black); a third is Neelok" (blue); the fourth yellow, &c. The unknown, or quantity sought, is called technically the *thing*, meaning emphatically the *thing* about which the question or enquiry is made. All their marks, denoting words expressing the operation, are Arabian. And it is remarkable that the first Italian writers on algebra, used a word of the same import for the unknown quantity, viz., *cosa*, the *thing*; whence, in Europe, the science came to be called the *cossic art*, and such quantities *cossic numbers*, &c.

There is also a character set next an unknown, to denote its square; another for the cube, &c; also a mark for the square root; and one for the cube root: but there does not appear to be any thing answering to a vinculum used in compound quantities. The higher powers are formed, and named, by repeating and combining these

marks; so, the 4th power is called the square square; the 5th power, the square cube; the 6th power, the cube cube; and so on, meaning those powers multiplied together. For equality they use the expression "I equalize," or "equalizing," and, indeed, all their operations are expressed in words at length.

When unknowns are multiplied together, they are placed next one another, in our manner; though there seems occasionally to be a mark for product. It is observable too that the affirmative, or the negative sign, and the coefficient, are always placed on contrary sides of the unknown, not $+2xy$, as with us, but $2xy+$, or $+xy2$; this latter is in the Persian way, as they read from right to left; but the Hindus from left to right, like the Europeans. But, though the Persians write from right to left, they do not use, or translate the Sanscrit numerals backwards; a circumstance which renders the opinion very probable, that the Persians derived their numeration characters and calculation from the Indians, but probably at second hand through the Arabians.

Compounds are multiplied as we fil the multiplication table: for example, to multiply $-3x + 2y - 2$ by $+4y - x + 1$, they proceed as in the margin, and afterwards collect the products.

In the process of their solutions, there is no distinct arrangement of the different steps, as in the modern algebra; but it is carried on without any breaks in the lines, something like de Burgo, or Bombelli, &c. The language is written in the first person, as,—I do so and so—I then equalize—next I multiply, &c.

We have already noticed their method of resolving compound quadratic equations, the same as ours, by completing the square; and better than ours in such cases as $ax^2 + bx = c$, when the first term has a coefficient a , which does not divide the two b and c , by which they avoid the operation in fractions. In imitation of this, also, I see they have a method of completing the powers in some cases of cubics and biquadratics: Thus, having the cubic equation $x^3 + 12x = 6x^2 + 35$; first subtracting $6x^2$, gives $x^3 - 6x^2 + 12x = 35$; next subtracting 8, gives $x^3 - 6x^2 + 12x - 8 = 27$, which completes the binomial cubic, and the roots are $x - 2 = 3$, or $x = 5$. Again, having given the imperfect biquadratic $x^4 - 400x - 2x^2 = 9999$, a case which it is not very obvious how to bring it to a complete power, but which is managed with much address, in this manner. First add $400x + 1$ to both sides, this gives $x^4 - 2x^2 + 1 = 10000 + 400x$, where the first side is a complete square, and the roots are $x^2 - 1 = \sqrt{(10000 + 400x)}$; but as the latter side is not a complete square, the author goes back again, and tries another course; thus, to the original equation he adds $4x^2 + 400x + 1$, which gives $x^4 + 2x^2 + 1 = 4x^2 + 400x + 10000$, two complete squares, the roots of which are $x^2 + 1 = 2x + 100$; again, subtract $2x$, and it becomes $x^2 - 2x + 1 = 100$, which are again two complete squares, the roots of which are $x - 1 = 10$, and hence $x = 11$. And this process has some resemblance to that which was afterwards practised, if not imitated, by Lewis Ferrari. It appears, however, that the Indians had no general method for all equations of these two powers, but only depended on their own ingenuity for artfully managing some particular cases of them; for, at the conclusion of the above process, the author emphatically adds, "The solu-

tion of such questions as these depends on correct judgment, aided by the assistance of God."

At the conclusion of the first book occur some curious circumstances in the solution of certain problems in the application of algebra to geometry, particularly some relating to right-angled triangles, by which it appears that they were well acquainted with the most remarkable properties in Euclid's Elements, some of which are cited under names peculiar to themselves, and sometimes, Mr. Strachey thinks, by numbers of the books and propositions in Euclid's collection, unless these last references have been added by the translator, or some transcriber, which is to be suspected.

In the 3d book the author comes to treat of questions and equations having several unknown quantities in them. These he directs to exterminate one after another, much after our modern way, till they are reduced to one unknown only. The number of independent equations are stated to be equal to the number of the unknown quantities; but when there are not so many equations, the defect is supplied by assuming values for as many of the unknown quantities, &c, as with us. The unknown quantities are represented and called by so many different characters and names, as is our own practice also. We denote them usually by the letters x , y , z , &c; the Hindus by different colours, or letters, or other marks also. "Thus," says our author, "suppose the first unknown, and the 2d black, and the 3d blue, and the 4th yellow, and the 5th red, and the 6th green, and the 7th parti-coloured, and so on, giving whatever names you please to the unknown quantities which you wish to discover; and if, instead of these colours, other names are supposed, such as letters, and the like, it may be done. For what is required, is to find out the unknown quantities, and the object in giving names, is that you may distinguish the things required."

In this 3d book occur many examples of making certain analytical expressions to be squares and cubes, &c. These are mostly very curious, many of them difficult, and often involving several unknown quantities; they are generally solved in a masterly way, and that very different from the manner of Diophantus. The two other books are on similar indeterminate problems, but gradually more and more complex and difficult.

Besides the above, there are many curious things in the Bija Ganita, and it may be presumed, adds Mr. Strachey, that the Hindu books contain much interesting matter respecting this branch of algebra; it is probable that they have some system of continued-fractions; and perhaps methods of approximation, and theories of series and equations. From the rules of the 5th book, and their application, there is some ground for an opinion, that the Hindus may have had a knowledge of curves, and much of the application of mathematics to natural philosophy.

On the whole, it would seem that the origin of algebra, as well as of arithmetic, was probably Indian. We have however as yet but little certain information on this subject. It has been said that the Arabs ascribe the invention of algebra to the Greeks; but the algebra of Diophantus is widely different from that of the Arabs; and it is very doubtful whether the Greeks ever had any other than that of Diophantus. If there be any doubt of Diophantus's algebra being of Greek origin, it may be worthy of remark, that at Alexandria he might have had the means of access

to Indian literature. The Bija Ganita is indeed of comparatively modern date; but we must not forget that it is extracted from other books, as stated by Mr. Davis, in the Asiatic Researches, in a very learned article on the cycle of 60 years. And it is not unlikely that there are old Hindu treatises, from which not only the Bija Ganita, but even the algebra of Diophantus, and that of the Arabs, may have been derived.

The other work, the Lilawati, as before mentioned, is on arithmetic, mensuration, &c. In the introduction, we find that "the collector of the book Lilawati was Bhasker Acharya, of Bidder city," on the northern confines of Hindustan. And "though the date of it is not known, yet in another book, made in the year 1105 of Salbahan, the reason of making the Lilawati is given." In the Ayeen Akbery (a Persian work on the manners, history, laws, &c, of the Hindus, translated by Gladwin), we find "that Acharya among the followers of Jine, is one who explains any difficulties that may occur to novices;" and therefore we may conclude that Bhasker was an instructor in mathematics. Now, the Salbahan, according to the Hindu chronology, commenced Anno Dom. 80; hence this book must have been written in 1185. But all that can be inferred from this is, that in 1185 they did not know when Bhasker lived.

The Lilawati begins with the first rules of arithmetic, and goes through fractions, the extraction of roots, &c, with a good deal of what we should call alligation. Like us, they mark every 3d figure from the place of units, in extracting the cube root. A part towards the end is upon "forms," somewhat similar it seems to our permutations. The numeral figures are nearly the same shape as those mentioned in p. 8 of Wallis's Algebra.

From which it appears that our present figures have been derived from them, by gradual and successive alterations in the shape, by different transcribers. And hence it appears also, that these figures, as well as their use, and the arts of arithmetic, algebra, &c, have come to us from India, in their progress through Persia, Arabia, Africa, Spain, Italy, &c; and that we ought rather to call them Indian figures, &c, than Arabian.

Translation of Fyzī's Preface to the Lilawati.

By order of the king Akber, Fyzī translates into Persian, from the Indian language, the book Lilawati, so famous for the rare and wonderful arts of calculation and mensuration. He (Fyzī) begs leave to mention, that the compiler of this book was Bhascāra Acharya, whose birth place, and the abode of his ancestors, was the city of Biddur, in the country of the Deccan. Though the date of compiling this work is not mentioned, yet it may be nearly known from the circumstance, that the author made another book on the Construction of Almanacks, called Kurrūn Kuttohul, in which the date of compiling it is mentioned to be 1105 years from the date of the Salibahn, an era famous in India. From that year, to this, which is the 32nd Jalihi year, corresponding with the Hejira year 995, there have passed 373 years." (answering nearly to 1585 of the Christian era).

It is said that the composing the Lilawati was occasioned by the following circumstance. Lilawati was the name of the author's (Bhascara's) daughter, concerning whom it appeared, from the qualities of the Ascendant at her birth, that she was destined to pass her life unmarried, and to remain without children. The father ascertained a lucky hour for contracting her in marriage, that she

might be firmly connected, and have children. It is said that when that hour approached, he brought his daughter and his intended son near him. He left the hour cup on the vessel of water, and kept in attendance a time-knowing astrologer, in order that when the cup should subside in the water, those two precious jewels should be united. But, as the intended arrangement was not according to destiny, it happened that the girl, from a curiosity natural to children, looked into the cup, to observe the water coming in at the hole; when by chance a pearl separated from her bridal dress, fell into the cup, and, rolling down to the hole, stopped the influx of the water. So the astrologer waited in expectation of the promised hour. When the operation of the cup had thus been delayed beyond all moderate time, the father was in consternation, and examining, he found that a small pearl had stopped the course of the water, and that the long-expected hour was passed. In short, the father, thus disappointed, said to his unfortunate daughter, I will write a book of your name, which shall remain to the latest times—for a good name is a second life, and the ground-work of eternal existence." Fyzī's preface then proceeds:

"The arrangement of this translation was made with the assistance of men learned in this science, particularly the astrologers of the Deccan. Some Indian words, for which corresponding expressions were not to be found in books of this science, have been retained, as they were in the Indian language. The work has been divided into an Introduction, some Rules, and a Conclusion."

Introduction. In this part are given explanations of some expressions in the science of calculation; with the meaning of certain terms employed in operations of the art of numbers; the divisions and terms of money, weights, measures, time, and mensurations; some of which are curious, as bearing some analogy to our own, of which they might possibly be the origin. The grain, or barleycorn, is given by the author, as the element of weights as well as measures. Thus, two barleycorns make 1 Soorkh. The breadth of 8 barleycorns is the quantity of 1 finger; 24 fingers make the Arm or cubit; and 10 cubits make a Bamboo or rod, nearly the same as our own. The element of time is given thus: The time in which a word of two letters, as *Ta* or *Ka*, can be uttered 10 times, "neither slowly nor quickly," is called Pran; then 6 prans make 1 Pul; 60 puls 1 Ghurry; and 60 ghurries one day and night. So that it hence appears that,

60 ghurries are	=	our 24 hours
1 ghurry	=	24 minutes
1 pul	=	24 seconds
1 pran	=	4 seconds
1 ka uttered in		$\frac{2}{3}$ of a second.

ON THE ARABIAN ALGEBRA.

Mr. Strachey says, "the Greek algebra may be seen in Diophantus, who is the only Greek writer on the subject that we have heard of.—The Indian algebra may be seen in Bija Ganita, and in the Lilawati, by the author of the Bija: and as the Persian translations of these works contain a degree of knowledge, which did not exist in any of the ordinary sources of science, extant in the time of the translators, they may be safely taken as Indian, and of ancient origin. To give some idea of the algebra of the Arabians, by which we may be enabled to judge whether, on the one hand, it could have been derived from Diophantus, or, on the other, that of the Hindus could have been

taken from them, the work entitled Khulasat-ul-Hisab, may be taken as a specimen; especially because there is a part of this book which marks the limits of algebraical knowledge, in the time of the writer.

" We have seen that the first European Algebraists learnt of the Arabians; but no account has been given of the nature, the extent, and the origin of Arabian algebra. No distinct abstract or translation of any Arabic book, on the subject, has appeared in print; nor has it been established beyond controversy, who taught the Arabians. The Khulasat-ul-Hisab is of considerable repute in India: it is thought to be the best treatise on algebra, and it is almost the only book on the subject read there. I selected it, because I understood that, as well as the shortest, it was the best treatise that could be procured. Besides general report, I was guided by the authority of Maulavi Roshen Ali, an acknowledged good judge of such matters, who assured me that, among the learned Moslems, it was considered as a most complete work, and that he knew of no Arabian algebra beyond what it contained. In the Sulafat-ul-Asr, a book of biography, by Nizam-ul-din Ahmed, there is this account of Baha-ul-din, the author of the Khulasat-ul-Hisab. ' He was born at Balbec, in the month of D'hi Ihaj, 953 Hijri, (anno Chr. 1575) and died at Isfahan in Shawal, 1031,' (anno Chr. 1653). Mention is made of many writings of Baha-ul-din, on religion, law, grammar, &c, a treatise on astronomy, and one on the astrolabe. In this list of his works, no notice is taken of his great treatise on algebra, the Behr-ul-Hisab, which is alluded to in the Khulasat-ul-Hisab. Mawlawi Roshen Ali tells me the commentators say, it is not extant. There is no reason to believe that the Arabians ever knew more than appears in Baha-ul-din's book, for their learning was at its height long before his time.

" From what has been stated it will appear, that from the Khulasat-ul-Hisab, an adequate conception may be formed of the nature and extent of the algebraical knowledge of the Arabians; and hence I am induced to hope, that a short analysis of its contents will not be unacceptable here. I deem it necessary here to state that, possessing nothing more than the knowledge of a few words in Arabic, I made the translation, from which the following summary is abstracted, from the *viva voce* interpretation into Persian of Maulavi Roshen Ali, who perfectly understood the subject and both languages, and afterwards collated it with a Persian translation, which was made about 60 years after Baha-ul-din's death, (anno Chr. 1713), and which Roshen Ali allowed to be perfectly correct.

" The work, as stated by the author in his preface, consists of an introduction, 10 books, and a conclusion. The introduction contains definitions of arithmetic, of number, which is its object, and of various classes of numbers. The author distinctly ascribes to the Indian sages the invention of the nine figures, to express the numbers from 1 to 9. Book 1 comprises the arithmetic of integers. The rules enumerated under this head are, Addition, Duplication, Subtraction, Halving, Multiplication, Division, and the Extraction of the Square Root. The method of proving the operation, by casting out the 9's is described under each of these rules. The author gives the following remarkable definitions of multiplication and division: viz, ' Multiplication is finding a number such, that the ratio which one of the factors bears to it, shall be the same which unity bears to the other factor; and division is finding a

number, which has the same ratio to unity, as the dividend has to the divisor.'

" For the multiplication of even tens, hundreds, &c, into one another, the author delivers the following rule, which is remarkable in this respect, that it exhibits an application of something resembling the indices of logarithms." ' Take the numbers as if they were units, and multiply them together, writing down the product, Then add the numbers of the ranks together, the place of units being 1, that of tens 2, &c; subtract 1 from the sum, and call the remainder the number of the rank of the product.' This is similar to our own practice in such cases, when we say, Multiply the significant numbers together, and subjoin to their product all the ciphers that are in both factors."

There next follow several other ingenious contrivances, and compendiums, such as, To multiply figures between 5 and 10. To multiply units into numbers between units and 20. To multiply together numbers between 10 and 20. To multiply numbers between 10 and 20 into compound numbers between 20 and 100, where the digits in the place of tens are the same. To multiply numbers between 10 and 100, when the digits in the place of tens are different. To multiply two unequal numbers, whose sum is even; from the square of the half sum subtract the square of the half difference. For multiplying numbers consisting each of several places of figures, the method described by this author, under the name of Shabacah, or network, and illustrated by the following example, has some resemblance to the operation by Napier's bones; where, instead of our way, the method is, to set down the whole of each product in the alternate chequers, then add up the columns diagonal wise. On the other rules, nothing is delivered differing so much from those contained in our common books of arithmetic, as to require particular mention.

Book 2d contains the arithmetic of fractions. Book 3d, the rule of three, or to find an unknown number by four proportions. Book 4th delivers the rule of position, both single and double, or to find an unknown number by assuming a number once or twice, and comparing the errors. Book 5th gives the method of finding an unknown number by reversing all the steps of the process described in the question. This last rule has a near affinity to the reduction of equations in algebra, and might very naturally lead to the invention of algebra itself, being easily and generally applicable to the solution of questions usually given in the rules of position, and in the reduction of equations. For instance, taking the first example in Double Position, in vol. 1, of my Course of Mathematics: viz, What number is that, which being multiplied by 6, the product increased by 18, and the sum divided by 9, the quotient shall be 20?

Now, beginning with the last result 20, and performing in a retrograde order all the reverse operations, they will be thus: because the last operation was *dividing* by 9, to give the result 20; and multiplication being the reverse of division, therefore *multiply* the result 20 by the 9, and it gives 180; then because the next preceding operation was *adding* 18, therefore *subtracting* 18 from the 180, leaves 162; lastly, because the next preceding operation was *multiplying* by 6, therefore *divide* the 162 by 6, and it gives 27, which must be the number sought, or that

first begun with. The proof is thus : $27 \times 6 = 162$, then $162 + 18 = 180$, and $180 \div 9 = 20$. Or thus, expressing all the operations by their respective marks or characters, it will give $\frac{27 \times 6 + 18}{9}$; now first multiplying by the divisor 9, gives $27 + 6 + 18$; then subtracting the increase 18, leaves $27 + 6$; and lastly, dividing by the divisor 6, must give the first or number required.

And this natural process is exactly the same as the general rule laid down at the beginning of Simple Equations in the same volume, as the most general and natural method for the reduction of all equations. Thus, assuming x for the number sought, in the same example : then by the question, $\frac{6x+18}{9} = 20$;

multiply by 9, and it becomes - - $6x + 18 = 180$;

subtract 18, and it is - - - $6x = 162$:

lastly, divide by 6, and it gives - - $x = 27$.

So that the mode of operation is exactly the same in all these ways.

Book 6th treats of Mensuration. The introduction contains geometrical definitions. Chap. 1 treats on the mensuration of rectilinear surfaces. Under this head, the two following articles are deserving of notice. 1st, To find the point in the base of a triangle, where it will be cut by a perpendicular, let fall from the opposite angle. Call the greatest side the base; multiply the sum of the two less sides by their difference; divide the product by the base, and subtract the quotient from the base; half the remainder will show the point on the base, where the perpendicular falls towards the least side. This property will easily be recognized as similar to that which we usually employ in resolving that case in plane trigonometry when the three sides are given, probably borrowed from the orientals; it is also the same property as that in the 35th theorem of my Geometry.

2nd, To find the area of an equilateral triangle. Multiply the square of a quarter of the square of one of the sides by 3; then the square root of the product is the area. That is, the side being a , its square is a^2 , the quarter of this is $\frac{1}{4}a^2$, the square of which is $\frac{1}{16}a^4$, multiplied by 3, it is $\frac{3}{16}a^4$, its root $\sqrt{\frac{3}{16}a^4}$ is the area. This is naturally derived from the property of right-angled triangles, and, by extracting the roots, soon reduces to $\frac{1}{4}a^2\sqrt{3}$, the same as our own rule for the same purpose.

Chap. 2nd treats on the mensuration of curvilinear surfaces. We here find the same rule for the area of the circle, as one of those employed by ourselves, for the same purpose, viz., multiply the square of the diameter by 11, and divide the product by 14.

Chap. 3d, on the mensuration of solids, contains nothing sufficiently remarkable to merit particular notice. This chapter concludes with the following sentence : 'The demonstrations of all these rules are contained in my greater work entitled Bahr-ul-Hisab (the ocean of calculations), may God grant me grace to finish it.'

Book the 7th treats on Practical Geometry. Of which, the first chapter is on levelling, for the purpose of making canals. In this are described the plummet-level, and the water-level, on the same principle with our spirit-level.

The 2nd chapter is on the mensuration of heights, accessible and inaccessible. Under the former of these heads are delivered the common methods, by bringing the top of a pole (whose height is known) in a line between the

eye and the top of the height required; or by viewing the image of the top in a horizontal mirror; also by taking the proportion between a perpendicular stick of known length, and its shadow; or by taking the length of the shadow of the height when the sun's altitude is 45 degrees. The concluding method is this: 'Place the index of the astrolabe at the mark of 45°, and stand at a place where the height of the object is seen through the sights; then measure from the place where you stand, to the place where a stone would fall from the top; add your own height, and the sum is the quantity required.'

For the mensuration of inaccessible heights, the following rule is delivered: 'Observe the top of the object through the sights, and mark on what shadow-line (division) the lower end of the index falls. Then move the index a step forward or backward, and advance or recede till you see the top of the object again. Measure the distance between your stations, and multiply by 7 if the index is moved a Dhil-Kadam, and by 12 if it is moved a Dhil-Asba, according to the shadow lines on the astrolabe; this is the quantity required.'

The 3d chapter is on measuring the breadth of rivers and depth of wells. Stand on the bank of the river, and through the two sights look at the opposite bank; then turn round and look at any thing on the land side, keeping the astrolabe even: the distance from the observer to the place is the same as the breadth of the river.

Book 8th is on finding unknown quantities by algebra. In this book are two chapters. The first is introductory, chiefly relating to the formation and operation of powers of the unknown quantity, thus. Call the unknown quantity Shai (thing), its product into itself Mal (possession), the product of Mal into Shai, Cab (a die or cube), of Shai into Cab, Mal-Mal; of Shai into Mal-i-Mal, Mal-Cab; Shai into Mal-i-Cab, Cab-i-Cab; and so on, without end. For one Cab write two Mals, and of these two Mals one becomes Cab; afterwards both Mals become Cab. Thus the 7th power is Mal-i-Mal-i-Cab, and the 8th Mal-i-Cab-i-Cab, in the 9th Cab-i-Cab-Cab, and so on. All these powers are in continued proportion, either ascending or descending. Thus the ratio of Mal-i-Mal to Cab, is like (or similar or equal to) the ratio of Cab to Mal, of Mal to Shai, and of Shai to 1, and of 1 to 1 divided by Shai, and of 1 divided by Shai to 1 divided by Mal, and of 1 divided by Mal to 1 divided by Cab, and of 1 divided by Cab to 1 divided by Mal-i-Mal. All this means, that all the terms in the successive powers are in continued proportion, viz, in our notation,

$$\frac{1}{x^4}, \frac{1}{x^3}, \frac{1}{x^2}, \frac{1}{x}, 1, x, x^2, x^3, x^4, \text{ &c,} \\ \text{or } x^{-4}, x^{-3}, x^{-2}, x^{-1}, x^0, x^1, x^2, x^3, x^4, \text{ &c.}$$

To multiply one of these powers by another. If they are both on the same side, (viz, of unity) add the exponents of their powers together; the product will have the same denomination as this sum. For example, to multiply Mal-i-Cab by Mal-i-Mal-i-Cab, the first is the 5th power, and the other is the 7th; the result then is Cab-i-Cab-i-Cab-i-Cab, or four Cabs, which is the 12th power. If the factors are on different sides, the product will be the excess on the side of the greater.—So, the product of 1 divided by Mal-i-Mal into Mal-i-Cab, is Shai; and the product of 1 divided by Cab-i-Cab-Cab into Cab-i-Cab-Mal-i-Mal, is 1 divided by Mal. And if the factors are at the same distance (from 1), the product is 1. The author

adds, "The particulars of the methods of division, with extraction of roots, and other rules, I have given in my greater book."

"The rules of algebra which have been discovered by learned men are six, and they relate to number and Shai and Mal." That is, to n and x and x^2 , including what we call simple and quadratic equations.

CHAPTER II. On the Six Rules of Algebra.

To find unknown quantities by algebra depends on acuteness and sagacity, with an attentive consideration of the terms of the question, and a successful application of the invention to such things as may serve to bring out the quantity required. Call the unknown quantity Shai (the Thing), and proceed with it according to the terms of the question, till the operation ends with an equation. Let that side where there are negative quantities be made perfect, adding the negative quantity to the other side, which is called restoration, *Jibr*, (hence doubtless, with the article *Al*, comes the name *Algebra*.) Let those things which are of the same kind, and equal on both sides, be thrown away which is called opposition (*Makabalah*).

Equality is either of one species to another, which is of three kinds, called simple (*Mufridat*), or of one species to two species, which is of three kinds, called compound (*Muktarinat*).

CASE 1st. *Mufridat*. When number is equal to *things* ($ax=n$); divide the number by the coefficient of the thing, and the unknown quantity will be found. *Example*. A person admitted that he owed to Zaid 1000 and one half of what he owed Amer; also that he owed Amer 1000 all but half of what he owed to Zaid. Call Zaid's debt Shai (x). Then Amer's debt is 1000 wanting half of Shai ($1000 - \frac{1}{2}x$); and Zaid's is 1500 wanting a fourth of Shai ($1500 - \frac{1}{4}x$). This is equal to Shai ($1500 - \frac{1}{4}x = x$). After *Jibr*, 1500 is equal to one Shai and a quarter of Shai ($1500 = 1\frac{1}{4}x$). So for Zaid is 1200, and for Amer 400.

CASE 2nd. *Multiples of Shai equal to multiples of Mal* ($ax=bx^2$). Divide the coefficient of the thing by that of Mal; the quotient is the unknown quantity ($\frac{a}{b}=x$). *Example*. Some sons plundered their father's inheritance, which consisted of Dinars. One took 1, another 2, the third 3, and so on increasing by 1. The ruling power took back what they had plundered, and divided it among them in equal shares, by which each received 7. How many sons were there, and how many Dinars? Suppose the number of Sons Shai (x), and take the sum of the extremes, viz., 1 and Shai ($1+x$). Multiply them by half of Shai ($\frac{1}{2}x$); this is the number of dinars ($\frac{1}{2}x + \frac{1}{2}x^2$); for the sum of any series of numbers in arithmetical progression, is equal to the product of the sum of the two extremes, into half the number of terms. Divide the number of the Dinars by Shai (x), which is the number of the sons, the quotient according to the terms of the question, will be $7(\frac{1}{2}x^2 + \frac{1}{2}x) \div x = 7$. Multiply 7 by Shai (x), the divisor, 7 Shai is the product, which is equal to $\frac{1}{2}$ Mal and $\frac{1}{2}$ Shai ($7x = \frac{1}{2}x^2 + \frac{1}{2}x$). After *Jibr* and *Mukabalah*, 1 Mal is equal to 13 Shai ($x^2 = 13x$); Shai then is 13 ($x = 13$); and this is the number of sons. Multiply this by 7, and the number of Dinars will be found 91.

It is added, that questions of this kind may be solved by position. "Thus, suppose the number of sons to be 5, the first error is 4 in defect; then suppose it to be 9, the

second error is 2 in defect. The first *Mafudh* is 10, and the second is 36; their difference is 26, and the difference of the errors is 2."—"Another method, which is short, is this: Double the quotient (7) to 14; subtract 1, and the result (13) is the number of sons."

CASE 3d. *Number equal to Mal* ($n=ax^2$). Divide the number by the coefficient of the Mal; the root of the quotient ($\sqrt{\frac{n}{a}} = x$) is the unknown quantity. *Example*. A person admitted that he owed Zaid the greater of two sums of money, the sum of which was 20, and the product 96. Suppose one of them to be 10 and Shai ($10 + x$), and the other 10 wanting Shai ($10 - x$). The product, which is 100 all but Mal ($100 - x^2$) is equal to 96; and after *Jibr* and *Mukabalah*, 1 Mal is equal to 4 ($x^2 = 4$), and Shai equal to 2 ($x = 2$). One of the sums then is 8, and the other 12, which is the debt of Zaid. Here, by substituting for the half-sum and half-difference the equation, comes out a simple one.

FIRST CASE OF *Maktarinat*. Number equal to Mal and Shai ($ax^2 + bx = n$). Complete the Mal to unit if it is deficient, or reduce it to the same if it exceeds, and reduce the number and Shai in the same ratio, by dividing all by the coefficient of the Mal. Then square one half the coefficient of the Shai, and add this square to the number. From the root of the sum subtract half the coefficient of the Shai, and the unknown will remain. An example follows as usual: and the method is evidently the same as ours at present.

CASE 2nd. Shai equal to number and Mal ($bx = x^2 + n$). After completing or rejecting, subtract the number from the square of half the coefficient of Shai; then add the root of the remainder to half the coefficient of the Shai, or subtract the former from the latter, and the result is the unknown quantity. This also is the same as the present method, and both the two roots are noticed in this case, by taking the root of the known quantity either positive or negative. An example is added as usual.

CASE 3d. Mal equal to number and Shai ($x^2 = n + bx$). After completion or rejection, add the square of half the coefficient of the Shai to the number, and add the root of the sum to half the coefficient of the Shai; this is the unknown quantity. *Example*. What number is that which being subtracted from its square, and the remainder added to its square, is 10? Subtract Shai from Mal and go on with the operation, than 2 Mal all but Shai is equal to 10 ($2x^2 - x = 10$); and after *Jibr* and *Radd*, Mal is equal to 5 and half of Shai ($x^2 = 5 + \frac{1}{2}x$). The square of half the coefficient of Shai and 5, is 5 and half an eighth ($\frac{5}{2}\frac{1}{8}$), and its root is $2\frac{1}{4}$; to this add $\frac{1}{4}$, the result $2\frac{1}{2}$ is the number sought.

Book 9th, contains 12 rules respecting the properties of numbers. As, 1st. To find the sum of the products multiplied into itself and into all numbers below it. Add 1 to the number; and multiply the sum by the square of the number; half the product is the number sought.

2nd. To add the odd numbers in their regular order. Add 1 to the last number, and take the square of half the sum.

3d. To add the even numbers from 2 upwards. Multiply half the last even number by a number greater by 1 than that half.

4th. To add the squares of the numbers in order. Add 1 to twice the last number, and multiply a 3d of the sum by the sum of the numbers.

5th. To find the sum of the cubes in succession. Take the square of the sum of the numbers.

6th. To find the product of the roots of two numbers. Multiply one by the other, and the root of the product is the answer.

7th. To divide the root of one number by that of another. Divide one by the other, the root of the quotient is the answer.

8th. To find a perfect number; that is, a number which is equal to the sum of its aliquot parts, (Eucl. book 7, def. 22). The rule is that delivered by Euclid, book 9, prop. 36.

9th. To find a square in a given ratio to its root. Divide the first number of the ratio by the second; the square of the quotient is the square required.

10th. If any number be multiplied and divided by another, the product multiplied by the quotient, is the square of the first number.

11th. The difference of two squares is equal to the product of the sum and difference of the roots.

12th. If two numbers be divided by each other, and the quotients multiplied together, the result is always 1.

Book 10th contains 9 practical examples, all of which are capable of solution by simple equations, or by position, or by retracing the steps of the operation, and some of them by simple proportion; so that it is needless to specify them.

The conclusion, which marks the limits of algebraical knowledge in the age of the writer, is here given entire, in the author's words.

"CONCLUSION. There are many questions in this science which learned men have to this time in vain attempted to solve; and they have stated some of these questions in their writings, to prove that this science contains difficulties, to silence those who pretend they find nothing in it above their ability, to warn arithmeticians against undertaking to answer every question that may be proposed, and to excite men of genius to attempt their solution. Of these I have selected seven.—1st. To divide 10 into two parts, such, that when each part is added to its square root, and the sums are multiplied together, the product is equal to a supposed number.—2d. What square number is that, which being increased or diminished by 10, the sum and remainder are both square numbers?—3d. A person said he owed to Zaid 10 all but the square root of what he owed to Amer, and that he owed Amer 5 all but the square root of what he owed Zaid.—4th. To divide a cube number into two cube numbers.—5th. To divide 10 into two parts such, that if each is divided by the other, and the two quotients are added together, the sum is equal to one of the parts.—6th. There are three square numbers in continued geometric proportion, such, that the sum of the three is a square number.—7th. There is a square, such, that when it is increased and diminished by its root and 2, the sum and the difference are squares.—Know, reader, that in this treatise I have collected in a small space the most beautiful and best rules of this science, more than were ever collected before in one book. Do not underrate the value of this bride; hide her from the view of those who are unworthy of her, and let her go to the house of him only who aspires to wed her."

From the preceding account of this Arabian treatise on Algebra, the Khulasat-ul-Hisab, of Baha-ul-din, which is esteemed the best in that language, we pretty clearly per-

ceive what was the state of science in that nation; that it was much the same as the first treatises among the Italians, derived directly from the former; but that it was much inferior to the same science among the Indians. It does not appear that the Arabians used algebraic notation or abbreviating symbols; that they had any knowledge of the Diophantine algebra, or of any but the easiest and elementary parts of the science. We have seen that Baha-ul-din ascribes the invention of the numeral figures, in the decimal scale, to the Indians; as is done indeed by all the Arabic and Persian books of arithmetic.

The following is an extract from a Persian treatise of arithmetic in Mr. Strachey's possession.

"The Indian sages wishing to express numbers conveniently, invented these nine figures, ۱ ۲ ۳ ۴ ۵ ۶ ۷ ۸ ۹ . The first figure on the right hand they made stand for units, the second for tens, the third for hundreds, the fourth for thousands. Thus, after the third rank, the next following is units of thousands, the second tens of thousands, the third hundreds of thousands, and so on. Every figure therefore in the first rank is the number of units it expresses; every figure in the second, the number of tens which the figure expresses; in the third, the number of hundreds; and so on. When in any rank a figure is wanting, write a cipher like a small circle (°) to preserve the rank. Thus, ten is written ۱۰, a hundred ۱۰۰, five thousand and twenty-five ۵۰۲۵."

In short, of the Indian algebra, in its full extent, the Arabians seem to have been ignorant; but most likely they had their algebra from the same source as their arithmetic. The Arabian and Persian treatises on algebra, like the first and old European ones, begin with arithmetic, called in those treatises the arithmetic of the Indians, and have a second part on algebra; but no notice is taken of the origin of the latter. Most likely their algebra, being numeral, was considered by the authors as a part of arithmetic.

Though part only of the Khulasat-al-Hisab, Mr. Strachey says, is concerning algebra, the rest, relating to arithmetic and mensuration, must be thought not wholly unconnected with the subject. It is to be hoped that ere long we shall have either translations from the Sanscrit of the Bij Ganita and Lilawati, or perfect accounts from the originals; and that other Hindu books of algebra will be found, and made known to the world. But in the mean time the Persian translations will be found well deserving of attention; observing carefully to distinguish between what is interpolated, and what is original.

From the preceding account of this Arabic treatise, also, is clearly seen the origin of the name of Algebra, being an Arabic compound, viz. of the article *al*, and *jebr*, which denotes one of the modes of reducing the equations, viz., by transposing or adding the negative terms, to make them all affirmative.

For a fuller account of the Indian and Arabian algebra, see my Tracts, vol. 2, p. 151, &c.

OF ALGEBRA IN ITALY AND OTHER PARTS OF EUROPE. We have seen that algebra had probably its rise in Hindustan, as well as our present numeration and arithmetic, all the rules of it having been found in the ancient MSS. of that country, much the same, in matter and form, as they appear in the first Italian authors; and among these, the two rules of false position, which are nearly al-

lied to algebra, and the extension of which probably led to, and ultimately became, the art of algebra itself. Hence it appears that these arts passed successively into Persia, Arabia, Africa, and Europe. In this last quarter it seems doubtful, whether their introduction was first into Spain or into Italy: the probability would appear to be on the side of the former, as it would most likely be introduced by the Moors on their settlement in the peninsula in the 8th, 9th, and 10th centuries; whence it might be communicated to Gaul and Germany and England, &c. This route is rendered the more probable by the circumstance, that the early state of the algebraic art in these countries was very different, and even more perfect, in several respects, than that in Italy, in the contemporary stages. And yet, on the other hand, against this probability of the first introduction of the art into Spain by means of the Moorish conquest, it may reasonably be objected, that it does not appear that the Arabians themselves had cultivated it at a time so early as the date of that conquest; and besides that we have not heard of any early works on Algebra having ever been found in the Spanish peninsula. It appears, however, at any rate, that Italy received the art by a different route, though probably at a later date, viz. immediately from the eastern Arabians themselves, without the knowledge of any other source or communication: and hence it was natural for the Italians to ascribe the invention of the art to that people.

It has usually been thought, that the first introduction of algebra into Italy, was about the 14th century. But we have lately, viz. in 1797, been favoured with a new and very diffuse history of algebra, by Sig. Cossali, in two large volumes, 4to, by which it appears, that the art was first imported into Italy, from the east, by Leonard Bonacci, of Pisa, who composed his arithmetic in the year 1202, and again in 1228; adding the algebra at the end, as a part of it.

In this work of Cossali's, accounts are given of several other old authors, as well Italian as Arabian and Persian, &c, among which some were much earlier than Leonard: as, a Mohamed ben Musa or Moses, called also Mohamed of Buziani, a place in Corasan, near the south-east point of the Caspian Sea. This Mohamed, it seems, in the year 959, travelled eastward to the confines of India, to learn the mathematical sciences, and afterwards to teach them; and who, according to Abulfaragio, in the year 969, wrote a Commentary on Diophantus; he wrote also Demonstrations of the Propositions in the same; and another work on the Universal Logistic Art, in three books.

It seems, however, that it was Leonard Bonacci, of Pisa, who first introduced the art in Italy, as before mentioned. Leonard's work, it appears, was a very orderly and regular treatise on arithmetic and algebra, as far as it was then known; teaching and demonstrating all the rules, and illustrating them with many examples; being also much occupied with questions about square and cube numbers, like those of Diophantus, or rather like what we have seen and described among the Indians and Arabians.—In algebra, Leonard distinguished three kinds of numbers, viz, the absolute known number in any question; then the unknown number, which he calls *radice*, the root; and its square, which he calls *census* in Latin, or *censo* in Italian; for his algebra extended only to the solution of equations of the 1st and 2d degree, the same as that of the Indians and Arabians. The language in which the work was written, was in barbarous Latin, or something

between Latin and Italian, when the language of the country was changing from the one to the other.

In treating his subject, Leonard had no such notation as is used by modern authors; on the contrary, he expressed every thing, both the quantities and the several operations, by their names, or words at full length. Those equations he treated of in six different forms, which are as follow, when expressed in the modern notation. 1st, $x^2 = ax$; 2d, $x^2 = n$; 3d, $ax = n$; 4th, $x^2 + ax = n$; 5th, $x^2 = ax + n$; 6th, $x^2 + n = ax$; where x denotes the *radice*, or quantity sought, x^2 its *censo* or square, a the number multiplying x , and n the absolute known number; and where it is remarkable that he places the terms, more or less, on the one side or the other, so as they may be all affirmative: all which cases and forms are exactly the same as before given by their masters the Arabians, &c.

Now omitting the simple forms, as including but little remarkable, we shall only consider the compound ones, or the solution of quadratic equations, by the method of completing the square, which Leonard finds on geometrical demonstration, as follows:—In the first case, if $x^2 + ax = n$, then the rule is $x = \sqrt{(\frac{1}{4}a^2 + n)} - \frac{1}{2}a$; which he thus demonstrates.

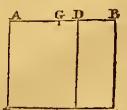

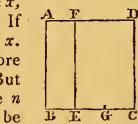

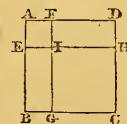

Demonstr. If upon a right line BC , greater than $\frac{1}{2}a$, the square $ABCD$ be constructed, on the sides of which there are taken the parts CG , CH , DF , BE , each equal to $\frac{1}{2}a$, and drawing the right lines EH , FG , intersecting in I , they form the square $IGCH = \frac{1}{4}a^2$. Supposing $EI = AP = EA = IF = BG = DH$, to denote the required quantity x ; then will the square AI or of $EI = x^2$, the rectangle $BI = \frac{1}{2}ax$ = also to the rectangle ID . Therefore the whole square $ABCD = x^2 + ax + \frac{1}{4}a^2$: but $x^2 + ax = n$; therefore is the same square $ABCD = n + \frac{1}{4}a^2$: consequently the side $BC = \sqrt{(n + \frac{1}{4}a^2)}$; and the quantity sought $x = BC - CG = BC - \frac{1}{2}a = \sqrt{(n + \frac{1}{4}a^2)} - \frac{1}{2}a$.

2ndly. If $x^2 = ax + n$; then will $x = \sqrt{(\frac{1}{4}a^2 + n)} + \frac{1}{2}a$.

Demonstr. Let the right line $BC = x$, and the square upon it $ABCD = x^2$. If CE be taken = a , and the perp. $EF = x$. Then the rectangle $FD = ax$. Therefore the remaining rectangle $AE = n$. But $AE = AB \times BE = BC \times BE$; therefore $n = BC \times BE = EE^2 + BE \times EC$. If EC be bisected in g , then will $n + EG^2 = BE^2 + BE \times EC + EG^2$. Hence $\sqrt{(n + EG^2)} = BE + EG$; and $GC + \sqrt{(n + EG^2)} = GC + BG$. So that, it being $GC = EG = \frac{1}{2}a$, and $BC = x$, it will be $\frac{1}{2}a + \sqrt{(n + \frac{1}{4}a^2)} = x$.

3dly. Let $x^2 + n = ax$.—Here he says, if $\frac{1}{4}a^2 < n$, the equation is impossible.—If $\frac{1}{4}a^2 = n$, then is $x = \frac{1}{2}a$.—If $\frac{1}{4}a^2 > n$, then is $x = \frac{1}{2}a - \sqrt{(\frac{1}{4}a^2 - n)}$, or $= \frac{1}{2}a + \sqrt{(\frac{1}{4}a^2 - n)}$.

Demonstr. Draw AB representing a , G , and unequally divided in D ; and upon one of the unequal parts, supposed = x , if there be made a square = x^2 . Now, if, in the first place, it be formed on the less part DB , supposed = x ; let FE be produced to I , till FI be = AB , and let AI be drawn. Then the whole rectangle $AF = AB \times BF = ax$; hence, taking away the square $BE = x^2$, there remains the rectangle $AE = AD \times DE = AD \times DB = n$; and adding to both the square GD^2 , gives $AD \times DB + GD^2 = n + GD^2$. But, by Eucl. II. 5, it

is $AD \times DB + GD^2 = BG^2$; therefore $BG^2 = n + GD^2$; hence $BG^2 - n = GD^2$, and $\sqrt{(BG^2 - n)} = GD$; then $BG - \sqrt{(BG^2 - n)} = BG - GD = DB$, or $\frac{1}{2}a - \sqrt{(\frac{1}{4}a^2 - n)} = x$. — If the square x^2 be constituted of the greater part AD , considered as $= x$; then by a like process it will be $\sqrt{(AG^2 - n)} = GD$; hence $AG + \sqrt{(AG^2 - n)} = AG + GD = AD$, that is $\frac{1}{2}a + \sqrt{(\frac{1}{4}a^2 - n)} = x$.

Thus we see that Leonard derived the rules for quadratic equations from geometrical considerations, and even the double values in the possible case of $x^2 + n = ax$; as it is probable his predecessors had done, and as we find his successors Lucas de Burgo and others did also. And this method shows the reason why these writers never admitted those values of x , in which n is greater than $\frac{4}{3}a^2$. We farther find, that neither Leonard, nor the Arabians, nor Indians, made any use of the form $x^2 + ax + n = 0$, nor of the negative roots of the two forms $x^2 + ax = n$, and $x^2 = ax + n$: it being Harriot who first departed from the usual custom (of equalizing the positive terms to the positive in an equation), by placing all the terms on one side, with their signs $+$ or $-$, and made $= 0$ on the other side, thus $x^2 \pm ax \pm n = 0$; and it was Cardan who had the honour of showing that, of the two forms $x^2 + ax = n$, and $x^2 = ax + n$, the negative root of the one is the positive root of the other.

It appears that Leonard Pisanus was well skilled in the various ways of reducing equations to their final simple state, by all the usual methods; as addition, subtraction, multiplication, division, powers and roots, to free them from radicals, &c. He was also well acquainted with the modes of substitution, so as to bring out the equation in the lowest degree; such as, in cases of two unknown quantities, instead of finding either of them separately, he would first search out their sum or difference. So, for instance, in this problem, "To divide the number 10 into two such parts, that from the greater part taking its own square-root, and to the less part adding its square root, the two results should be equal." Now, in this case, if in the common way x be made to denote one of the parts, as the greater suppose, then $10 - x$ will denote the less part, and the equation will be $x - \sqrt{x} = 10 - x + \sqrt{(10 - x)}$, the reduction of which leads to a complete equation of the 4th degree. But, instead of this method, Leonard employs the way of the half-sum and half-difference, as used by Diophantus and the Arabians and Hindus, which has been accounted by some persons an artifice of the modern algebraists. Thus, if x be put to denote the half-difference of the two parts; then 5 being their half-sum, $5 + x$ will be the greater, and $5 - x$ the less, and the equation will be $5 + x - \sqrt{(5 + x)} = 5 - x + \sqrt{(5 - x)}$, which reduces to a final quadratic, as is done by this author.

From Pisa, as from a centre, it seems the art gradually spread through Tuscany and all Italy; in consequence of which, many other authors in that country had respectable names before the period of the art of printing. So, we read that Raffaello Canacci, a Florentine mathematician, was author of a "Ragionamento di Algebra," who praises another that preceded him, named Guglielmo di Lunis; of whom Casacci writes, at the beginning of his Ragionamento, "La regola dell'algebra, la quale regola Ghughelmo di Lunis la translato d'Arabico a nostra lingua;" whence some have thought, though without probability, that the honour of having made Italy acquainted with algebra was due to Guglielmo di Lunis, rather than to Leonardo Bonacci di Pisa. Many other early authors are mentioned.

Bombelli, in the preface to his book, writes that a work of Mohamed ben Musa had been shown, but it was of little value. And it is said that Lucas de Burgo, the first author in print, was instructed in this science at Venice, by Domanico Bragadini, successor in the public chair to the learned Paolo della Pergola, his preceptor, who died in 1366.

Proceed we now to the consideration of the books of Lucas de Burgo, and other authors, whose works we are possessed of in print.

LUCAS PACIOLUS, OR DE BURGO.

It was chiefly among the Italians that this art was first cultivated in Europe. And, the first author whose works were in print, was Lucas Pacioli, or Lucas de Burgo, a cordelier, or minorite friar. He wrote several treatises of arithmetic, algebra, and geometry, which were printed in the years 1470, 1476, 1481, 1487, and in 1494 his principal work, entitled *Summa de Arithmetica, Geometria, Proportioni, et Proportionalita*, which is a very masterly and complete treatise on those sciences, as they then stood. In this work he mentions various former writers, as Euclid, St. Augustine, Sacrobosco or Halifax, Boetius, Prodicomo, Giordano, Biagio da Parma, and Leonardus Pisanius, from whom he learned those sciences.

The order of the work is, 1st arithmetic, 2d algebra, and 3d geometry. Of the arithmetic, the contents, and the order of them, are nearly as follow. First, of numbers figurate, odd and even, perfect, prime and composite, and many others. Then of common arithmetic in seven parts, namely, numeration or notation, addition, subtraction, multiplication, division, progression, and extraction of roots. Before him, he says, duplication and mediation, or doubling and halving, were accounted two rules in arithmetic; but that he omits them, as being included in multiplication and division. He ascribes the present notation and method of arithmetic to the Arabs; and says that according to some the word Abaco is a corruption of Modo Arabico, but that according to others it was from a Greek word. This, however, must be a mistake; for though the Italians had those arts from the Arabs, these latter had them probably from the Indians. All those primary operations he both performs and demonstrates in various ways, many of which are not in use at present; proving them not only by what is called casting out the nines, but also by casting out the sevens, and otherwise. In the extraction of roots he uses the initial \mathbb{R} for a root; and when the roots can be extracted, he calls them discrete or rational; otherwise surd, or indiscriminate, or irrational. The square root is extracted much the same way as at present, namely, dividing always the last remainder by double the root found; and so he continues the surd roots continually nearer and nearer in vulgar fractions. Thus, for the root of 6, he first finds the nearest whole number 2, and the remainder 2 also; then $\frac{2}{2}$ or $\frac{1}{2}$ is the first correction, and $2\frac{1}{2}$ the second root: its square is $6\frac{1}{4}$; therefore $\frac{1}{4}$ divided by 5, or $\frac{1}{20}$, is the next correction, and $2\frac{1}{2}$ minus $\frac{1}{20}$, or $2\frac{9}{20}$ is the 3d root: its square is $6\frac{1}{400}$; therefore $\frac{1}{400}$ divided by 4 $\frac{1}{20}$, or $\frac{1}{80}$, is the 3d correction, which gives $2\frac{991}{1600}$ for the 4th root, whose square exceeds 6 by only $\frac{3341}{160000}$: and so on continually: and this process he calls approximation. He observes that fractions, which he sets down the same way as we do at present, are extracted, by taking the root of the denominator, and of the denominated, for so he calls the numerator: and when mixed numbers occur, he directs to re-

duce the whole to a fraction, and then extract the roots of its two terms as above: as if it be $12\frac{1}{4}$; this he reduces to $\frac{49}{4}$, and then the roots give $\frac{7}{2}$ or $3\frac{1}{2}$: in like manner he finds that $4\frac{1}{2}$ is the root of $20\frac{1}{4}$; $5\frac{1}{2}$ the root of $30\frac{1}{4}$; " and so on (he adds) in infinitum"; which shows that he knew how to form the series of squares by addition. He then extracts the cube root, by a rule much the same as that which is used at present; from which it appears that he was well acquainted with the co-efficients of the binomial cubed, namely, 1, 3, 3, 1; and he directs how the operation may be continued "in infinitum" in fractions, like as in the square root. After this, he describes geometrical methods for extracting the square and cube roots instrumentally: he then treats professedly of vulgar fractions, their reductions, addition, subtraction, and other operations, much the same as at present: then of the rule-of-three, gain-and-loss, and other rules used by merchants.

Paciolus next enters on the algebraical part of this work, which he calls "L'Arte Magiore; ditta dal vulgo la Regola de la Cosa, over Algebreia e Almucabala;" which last name he explains by *restauratio et oppositio*, and assigns as a reason for the first name, that it treats of things above the common affairs in business, which make the *arte minore*. Here he mistakenly ascribes the invention of algebra to the Arabians; and he says that the Arabian algebra means in Italian position, or rather opposition. He denominates the series of powers, with their marks or abbreviations, as n^o , or *numero*, the absolute or known number; *co.* or *cosa*, the thing or 1st power of the unknown quantity; *ce.* or *censo*, the product or square; *cu.* or *cubo*, the cube, or 3d power; *ce. ce.* or *censo de censo*, the square-squared, or 4th power; *p^o.* *r^o*, or *primo relato*, or 5th power; *ce. cu.* or *censo de cubo*, the square of the cube, or 6th power; and so on, compounding the names or indices according to the multiplication of the numbers 2, 3, &c, and not according to their sum or addition, as used by Diophantus, with the Arabians and Indians. He describes also the other characters made use of in this part, which are for the most part no more than the initials or other abbreviations of the words themselves, after the manner of the Indians; as for *R^o radici*, the root; *R^o. R^o radici de radici*, the root of the root; *R^o. u. radici universale*, or *radici legitata*, or *radici unita*; *R^o cu. radici cuba*; and *q^o3 quantita*, quantity; *p* for *piu* or plus, and *m* for *meno* or minus; and he remarks that the necessity and use of these two last characters are for connecting, by addition or subtraction, different powers together; as $3 \text{ cosa} . 4 \text{ censu} . m . 5 \text{ cubo} . p . 2 \text{ ce. ce. m. } 6 \text{ n}^o$, that is, 3 cosa, piu 4 censa, meno 5 cubo, piu 2 censa-censa, meno 6 numeri, or, as we now write the same thing, $3x + 4x^2 - 5x^3 + 2x^4 - 6$.

He first treats very fully of proportions and proportionality, both arithmetical and geometrical, accompanied with a large collection of questions concerning numbers in continued proportion, resolved by a kind of algebra. He then treats of *el Cataym*, which he says, according to some, is an Arabic or Phenician word, and signifies the Double Rule of False Position: but he here treats of both single and double position, as we do at present, dividing the *el Cataym* into single and double, as the Arabians and Indians did. He gives also a geometrical demonstration of both the cases of the errors in the double rule, namely, when the errors are both plus or both minus, and when the one error is plus and the other minus; and adds a large collection of questions, as usual. He then goes

through the common operations of algebra, with all the variety of signs, as to plus and minus; proving that, in multiplication and division, like signs give plus, and unlike signs give minus. He next treats of different roots in *infinitum*, and the extraction of roots; giving also a copious treatise on radicals or surds, as to their addition, subtraction, multiplication, and division, and that both in square roots and cube roots, and in the two together, much the same as at present. He makes here a digression concerning the 15 lines in the 10th book of Euclid, treating them as surd numbers, and teaching the extraction of the roots of the same, or of compound surds or binomials, such as of $23 p R 448$, or of $R 18 p R 10$; and gives this rule, among several others, namely: Divide the first term of the binomial into two such parts, that their product may be $\frac{1}{4}$ of the number in the second term; then the roots of those two parts, connected by their proper sign *p* or *m*, is the root of the binomial; as in this $23 p R 448$, the two parts of 23 are 7 and 16, whose product, 112, is $\frac{1}{4}$ of 448, therefore their roots give $4 p R 7$ for the root $R u. 23 p R 448$.

He next treats of equations both simple and quadratic, or simple and compound, as he calls it; and this latter he performs by completing the square, and then extracting the root, just as usual. He also resolves equations of the simple 4th power, and of the 4th combined with the 2d power, which he treats the same way as quadratics; expressing his rules in a kind of bad verse, and giving geometrical demonstrations of all the cases, the same as those of Leonard of Pisa, before described. He uses both the roots or values of the unknown quantity, in that case of the quadratics which has two positive roots; but he takes no notice of the negative roots in the other two cases. As to any other compound equations, such as the cube and any other power, or the 4th and 1st, or 4th and 3d, &c, he gives them up as impossible, or at least he says that no general rule has yet been found for them, any more, he adds, than for the quadrature of the circle.—The remainder of this part is employed on rules in trade and merchandise, such as Fellowship, Barter, Exchange, Interest, Composition or Alligation, with various other cases in trade. And in the third part of the work, he treats of Geometry, both theoretical and practical.

From this account of Lucas de Burgo's book, we may perceive what was the state of algebra about the year 1500, in Europe; and probably it was much the same in Africa and Arabia, whence the Europeans had it. It appears that their knowledge extended no farther than quadratic equations, of which they used only the positive roots; that they used only one unknown quantity; that they had no marks or signs for either quantities or operations, excepting only some few abbreviations of the words or names themselves; and that the art was only employed in resolving certain numeral problems. So that either the orientals had not carried algebra beyond quadratic equations, or else the Europeans had not learned the whole of the art, as it was then known to the former. And indeed it is not impossible but this might be the case: for whether the art was brought to us by an European, who, travelling into the East, there learned it; or whether it was brought to us by those people; in either case we might receive the art only in an imperfect state, and perhaps far short of the degree of perfection to which it had been carried by their best authors. And this suspicion is rendered rather probable by the circumstance of an Arabic manuscript, said

to be on cubic equations, deposited in the library of the university of Leyden by the celebrated Warner, bearing a title, which in Latin signifies *Omar Ben Ibrahim al'Ghamama Algebra cubicarum æquationum, sive de problematum solidorum resolutione.* At any rate, however, we have found that the Hindus, if not the Arabians, treated of problems including several unknown quantities, with applications of algebra to geometrical and to indeterminate problems.

FERREUS AND CARDAN.

After the publication of the books of Lucas de Burgo, the science of algebra became more generally known, and improved, especially by many persons in Italy; and about this time, or soon after, namely, about the year 1505, the first rule was there found out by Scipio Ferreus, for resolving one case of a compound cubic equation. But this science, as well as other branches of mathematics, was most of all cultivated and improved there by Hieronymus Cardan of Bononia, a very learned man, whose arithmetical writings were the next that appeared in print, namely, in the year 1539, in nine books, in the Latin language, at Milan, where he practised physic, and read public lectures on mathematics; and in the year 1545 came out a 10th book, containing the whole doctrine of cubic equations, which had been in part revealed to him by Tartalea, about the time of the publication of his first nine books. And as it is only this 10th book which contains the new discoveries in algebra, I shall here confine myself to it alone, as it will also afford sufficient occasion to speak of his manner of treating algebra in general. This book is divided into 40 chapters, in which the whole science of cubic equations is most amply and ably treated. Chap. 1, treats of the nature, number, and properties, of the roots of equations, and particularly of single equations that have double roots. He begins with a few remarks on the invention and name of the art: calls it *Ars Magna, or Cosa, or Rules of Algebra,* after Lucas de Burgo and others: says it was invented by Mahomet, the son of one Moses, an Arabian, as is testified by Leonardus Pisanus; and that he left four rules or cases, which only included quadratic equations: that afterwards three derivatives were added by an unknown author, though some think by Lucas Pacioli; and after that again three other derivatives, for the cube and 6th power, by another unknown author; all which were resolved like quadratics: that then Scipio Ferreus, professor of mathematics at Bononia, about 1505, found out the rule for the case *cubum et rerum numero æqualium*, or, as we now write it, $x^3 + bx = c$, which he speaks of as something admirable: that the same thing was next afterwards found out, in 1535, by Tartalea, who revealed it to him, Cardan, after the most earnest entreaties: that finally, by himself and his quondam pupil Lewis Ferrari, the cases were greatly augmented and extended, namely, by all that is not here expressly ascribed to others; and that all the demonstrations of the rules are his own, except only three adopted from Mahomet for the quadratics, and two of Ferrari for cubics.

Cardan then delivers some remarks, showing that all square numbers have two roots, the one positive, and the other negative, or, as he calls them, *vera et ficta*, true and fictitious or false; so the *æstimatio rei*, or root, of 9, is either 3 or -3; of 16 it is 4 or -4; the 4th root of 81 is 3 or -3; and so on for all even denominations or powers. And the same is remarked on compound cases of even powers that are added together; as if $x^4 + 3x^2 = 28$, then

the *æstimatio x* is = 2 or -2; but that the form $x^4 + 12 = 7x^2$ has four answers or roots, in real numbers, two plus and two minus, viz. 2 or -2, and $\sqrt{3}$ or $-\sqrt{3}$; while the case $x^4 + 12 = 6x^2$ has no real roots; and the case $x^4 = 2x^2 + 8$ has two, namely, 2 and -2; and in like manner for other even powers. So that he includes both the positive and negative roots; but rejects what we now call imaginary ones. I here express the cases in our modern notation, for brevity sake, as he commonly expresses the terms by words at full length, calling the absolute or known term the *numero*, the 1st power the *res*, the 2d the *quadratum*, the 3d the *cubum*, and so on, using no mark for the unknown quantity, and only the initials *p* and *m* for plus and minus, and *R* for radix or root. The *res* he sometimes calls *positio* (as derived from the like quantity in the rule of position), and *quantitas ignota*; and in stating or setting down his equations, he as well as Lucas de Burgo before him, sets down the terms on that side where they will be plus, and not minus.

On the other hand, he remarks that the odd denominations, or powers, have only one *æstimatio*, or root, and that true or positive, but none fictitious or negative, and for this reason, that no negative number raised to an odd power, will give a positive number; so of $2x = 16$, the root is 8 only; and if $2x^3 = 16$, the root is 2 only; and if there be ever so many odd denominations, added together, equal to a number, there will be only one *æstimatio* or root; as if $x^3 + 6x = 20$, the only root is 2. But that when the signs of some of the terms are different, as to plus and minus, they may have more roots; and he shows certain relations of the coefficients, when they have two or more roots: so the equation $x^3 + 16 = 12x$ has two *æstimatos*, the one true or 2, and the other fictitious or -4, which he observes is the same as the true *æstimatio* of the case $x^3 = 12x + 16$, having only the sign of the absolute number changed from the former, the 3d root 2 being the same as the first, which therefore he does not count. He next shows what are the relations of the coefficients when a cubic equation has three roots, of which two are true, and the 3d fictitious, which is always equal to the sum of the other two, and also equal to the true root of the same equation with the sign of the absolute number changed: thus, in the equation $x^3 + 9 = 12x$, the two true roots are 3 and $\sqrt{5\frac{1}{4}} - 1\frac{1}{2}$, and the fictitious one is $-\sqrt{5\frac{1}{4}} - 1\frac{1}{2}$, which last is the same as the true root of $x^3 = 12x + 9$, viz., $\sqrt{5\frac{1}{4}} + 1\frac{1}{2}$; and he here infers generally that the fictitious *æstimatio* of the case $x^3 + c = bx$, always answers to the true root of $x^3 = bx + c$. Cardan also shows what the relation of the coefficients is, when the case has no true roots, but only one fictitious root, which is the same as the true root of the reciprocal case, formed by changing the sign of the absolute number. Thus, the case $x^3 + 21 = 2x$ has no true root, and only one false root, viz., -3, which is the same as the true root of $x^3 = 2x + 21$; and he shows in general, that changing the sign of the absolute number in such cases as want the 2d term, or changing the signs of the even terms when it is not wanting, changes the signs of all the three roots, which he also illustrates by many examples; thus, the roots of $x^3 + 11x^2 = 72$, are $+\sqrt{40 - 4}$, and -3, and $-\sqrt{40 - 4}$; and the roots of $x^3 + 72 = 11x^2$, are $-\sqrt{40 + 4}$, and +3, and $+\sqrt{40 + 4}$.

And he further observes, that the sum of the three roots, or the difference between the true and fictitious roots, is equal to 11, the coefficient of the 2d term. 11c

also shows how certain cubic cases have one, or two, or three roots, according to circumstances: that the case $x^3 + d = bx^2$ has sometimes four roots, and sometimes none at all; that is, no real ones: that the case $x^3 + bx = ax^2 + c$ may have three true estimations, or positive roots, but no fictitious or negative ones; and for this reason, that the odd powers of minus being minus, and the even powers plus, the two terms $x^3 + bx$ would be negative, and equal to a positive sum $ax^2 + c$, which is absurd: and further, that the case $x^3 + ax^2 + bx = c$ has three roots, one plus and two minus, which are the same, with the signs changed, as the roots of the case $x^3 + bx + c = ax^2$. He also shows the relation of the coefficients when the equation has only one real root, in a variety of cases: but that the case $x^3 + c = ax^2 + bx$ has always one negative root, and either two positive roots, or none at all; the number of roots failing by pairs, or the impossible roots, as we now call them, being always in pairs. Of all these circumstances Cardan gives a great many particular examples in numeral coefficients, and subjoins geometrical demonstrations of the properties here enumerated; such as, that the two corresponding or reciprocal cases have the same root or roots, but with different signs or affections; and how many true or positive roots each case has.

On the whole, it appears from this short chapter, that Cardan had discovered most of the principal properties of the roots of equations, and could point out the number and nature of the roots, partly from the signs of the terms, and partly from the magnitude and relations of the coefficients. He shows in effect, that when the case has all its roots, or when none are impossible, the number of its positive roots is the same as the number of changes in the signs of the terms, when they are all brought to one side: that the co-efficient of the 2d term is equal to the sum of all the roots positive and negative collected together, and consequently that when the 2d term is wanting, the positive roots are equal to the negative ones: and that the signs of all the roots are changed, by changing only the signs of the even terms: with many other just remarks concerning the nature of equations.

In chap. 2, Cardan enumerates all the cases of compound equations of the 2d and 3d order, namely 3 quadratics, and 19 cubics; with 44 derivatives of these two, that is, of the same kind, with higher denominations.

In chap. 3 are treated the roots of simple cases, or simple equations, or at least that will reduce to such, having only two terms, the one equal to the other. He directs to depress the denominations equally, as much as they will, according to the height of the least; then divide by the number or coefficient of the greatest; and lastly extract the root on both sides. So if $20x^3 = 180x^5$, then $20 = 180x^2$, and $\frac{2}{9} = x^2$, and $x = \frac{\sqrt{2}}{3}$.

Chap. 4 treats of both general and particular roots, and contains various definitions and observations concerning them. It is here shown, that the several cases of quadratics and cubics have their roots of the following forms or kinds, namely, that the case

$x^2 = ax + b$ has its root of this kind $\sqrt{19 + 3}$,
 $x^2 + ax = b$ has its root of this kind $\sqrt{19 - 3}$,
 $x^2 + b = ax$ has two roots like $3 + \sqrt{2}$ and $3 - \sqrt{2}$,
 $x^3 = bx + c$ has its root of this kind $\sqrt[3]{4} + \sqrt[3]{2}$,
 $x^3 + bx = c$ has its root of this kind $\sqrt[3]{4} - \sqrt[3]{2}$,
 $x^3 = ax^2 + c$ has this kind of root $\sqrt[3]{16 + 2 + \sqrt[3]{4}}$,
 $x^3 + ax^2 = c$ has this kind of root $\sqrt[3]{16 - 2 + \sqrt[3]{4}}$,
where the three parts $\sqrt[3]{16}$, 2 , $\sqrt[3]{4}$, are in continual proportion.

Chap. 5 treats of the *estimatio* of the lowest degree of compound cases, that is, affected quadratic equations; giving the rule for each of the three cases, which consists in completing the square, &c., as at present, and which was the method given by the Arabians and Hindus; and proving them by geometrical demonstrations from Euc. i, 43, and ii, 4 and 5; in which he makes some improvement on the demonstrations of Mahomet. And hence it appears that the work of this Arabian author was in being, and well known in Cardan's time.

Chap. 6, on the methods of finding new rules, contains some curious speculations concerning the squares and cubes of binomial and residual quantities, and the proportions of the terms of which they consist, shown from geometrical demonstrations, with many curious remarks and properties, forming a foundation of principles for investigating the rules for cubic equations.

Chap. 7 is on the transmutation of equations, showing how to change them from one form to another, by taking away certain terms out of them; as $x^3 + ax^2 = c$, to $x^3 = bx + d$, &c. The rules are demonstrated geometrically; and a table is added, of the forms into which any given cases will reduce; which transformations are extended to equations of the 4th and 5th order. And hence it appears that Cardan knew how to take away any term out of an equation.

Chap. 8 shows generally how to find the root of any such equation as this, $ax^m = x^n + b$, where m and n are any exponents whatever, but n the greater; and the rule is, to separate or divide the coefficient a into two such parts z and $a-z$, as that the absolute number b shall be equal to $\frac{m}{(a-z) \cdot z^{n-m}}$, the product of the one part $a-z$, and the $\frac{m}{n-m}$ power of the other part: then the root x is = $\frac{1}{\sqrt[n-m]{z^{n-m}}}$.

The rule is general for quadratics, cubics, and all the higher powers: and could not have been formed without the knowledge of the composition of the terms from the roots of the equation.

Chap. 9 and 10 contain the resolution of various questions producing equations not higher than quadratics.

Chap. 11 is on the case or form $x^3 + 3bx = 2c$. Cardan now comes to the actual resolution of the first case of cubic equations. He begins with relating a short history of the invention of it, observing that it was first found out, about thirty years before, by Scipio Ferreus, of Bononia, and by him taught to Antonio Maria Florido, of Venice, who having a contest afterwards with Nicolas Tartalea, of Brescia, it gave occasion to Tartalea to find it out himself, who after great entreaties taught it to Cardan, but suppressed the demonstration. By help of the rule alone, however, Cardan of himself discovered the source or geometrical investigation, which he gives here at large, from Euc. ii, 4. In this process he makes use of the Greek letters α , β , γ , δ , &c., to denote certain indefinite numbers or quantities, to render the investigation general; which may be considered as the first instance of such literal notation in algebra. He then gives the rule in words at length, which comes to this, $x = \sqrt[3]{[\sqrt{(c^2 + b^2)} + c]} - \sqrt[3]{[\sqrt{(c^2 + b^2)} - c]}$; illustrating it by a variety of examples; in the resolution of which, he extracts the cubic roots of such of the binomials as will admit of it, by some rule which he had for that purpose; such as $x^3 + 6x = 20$, where $x = \sqrt[3]{(\sqrt{108 + 10})} - \sqrt[3]{(\sqrt{108 - 10})} = (\sqrt[3]{108 + 1}) - (\sqrt[3]{108 - 1}) = 2$.

Chap. 12, on the case $x^3 = 3bx + 2c$. This he treats exactly as the last, and finds the rule to be $x = \sqrt[3]{c + \sqrt{(c^2 - b^2)}} + \sqrt[3]{c - \sqrt{(c^2 - b^2)}}$; which he illustrates by many examples, as usual. But when b^3 exceeds c^2 , which has since been called the irreducible case, he refers to another following book, called *Aliza*, for other rules of solution, to overcome this difficulty, about which he took infinite pains.

Chap. 13, on the case $x^3 + 2c = 3bx$. This case, by a geometrical process, he reduces to the case in the last chapter: thus, find the astigmatio y of the case $y^3 = 3by + 2c$, having the same coefficients as the given case $x^3 + 2c = 3bx$; then is $x = \frac{1}{3}y \pm \frac{1}{3}\sqrt{(12b - 3y^2)}$, giving two roots. He shows also how to find the second root, when the first is known, independent of the foregoing case. From this relation of these two cases he deduces several corollaries, one of which is, that the astigmatio or root of the case $y^3 = 3by + 2c$, is equal to the sum of the roots of the case $x^3 + 2c = 3bx$. As in the example $y^3 = 16y + 21$, whose astigmatio is $\sqrt[3]{\frac{1}{4}} + \frac{1}{2}$, which is equal to the sum of 3 and $\sqrt[3]{\frac{1}{4} - \frac{1}{2}}$, the two roots of the case $x^3 + 21 = 16x$.

In chapters 14, 15, and 16, he treats of the three cases, which contain the 2d and 3d powers, but wanting the 1st power, according to all the varieties of the signs; which he performs by exterminating the 2d term, or that which contains the 2d power of the unknown quantity x , by substituting $y \pm \frac{1}{3}$ the coefficient of that term for x , and so reducing these cases to one of the former. In these chapters Cardan sometimes also gives other rules; thus, for the case $x^3 + 3ax^2 = 2c$, find first the astigmatio y of the case $y^3 = 3ay + \sqrt{2c}$, then is $x = y^2 - 3a$: also for the case $x^3 + 2c = 3ax^2$, first find the two roots of $y^3 + 2c = 3ay + \sqrt{2c}$, then is $x = \frac{\sqrt[3]{4c^2}}{y}$ the two values of x according to the two values of y . He here also gives another rule, by which a second astigmatio or root is found, when the first is known, namely, if e be the first astigmatio, or value of x in the case $x^3 + 2c = 3ax^2$, then is the other value of $x = \frac{1}{2}\sqrt[(3a - e) \cdot (3a + 3e)] + \frac{1}{2}(3a - e)$.

In chapters 17, 18, 19, 20, 21, 22, 23, Cardan treats of the cases in which all the four terms of the equation are present; and this he always effects by taking away the 2d term out of the equation, and so reducing it to one of the foregoing cases which want that term, giving always geometrical investigations, and adding a great many examples of every case of the equations.

Chap. 24 is on the 44 derivative cases; which are only higher powers of the forms of quadratics, and cubics.

Chap. 25, on imperfect and special cases; containing many particular examples when the coefficients have certain relations among them, with easy rules for finding the roots; also 8 other rules for the irreducible case $x^3 = bx + c$.

Chap. 26, in like manner, contains easy rules for biquadratics, when the coefficients have certain special relations.

Then the following chapters, from chap. 27 to chap. 38, contain a great number of questions and applications of various kinds; the titles of which are these: *De transitu capituli specialis in capitulum speciale*; *De operationibus radicum pronicarum seu mixtarum et Allellarum*; *De regula modi*; *De regula Aurea*; *De regula Magna*, or the method of finding out solutions to certain questions; *De regula aquilis positionis*, being a method of substituting for the half sum and half difference of two quantities instead of

the quantities themselves; *De regula inqualiter ponendi*, *seu proportionis*; *De regula mediæ*; *De regula aggregati*; *De regula libera positionis*; *De regula falsum ponendi*, in which some quantities come out negative; *Quomodo excidunt partes et denominaciones multiplicando*. Among the foregoing collection of questions, which are chiefly about numbers, there are some geometrical ones, being the application of algebra to geometry; such as, In a right-angled triangle, given the sum of each leg and the adjacent segment of the hypotenuse, made by a perpendicular from the right angle, to determine the area, &c.; with other such geometrical questions, resolved algebraically.

Chap. 39, *De regula qua pluribus positionibus inventimus ignorantem quantitatem*; which is employed on biquadratic equations. After some examples of his own, Cardan gives a rule of Lewis Ferrari's, for resolving all biquadratics, namely, by means of a cubic equation, which Ferrari investigated at his request, and which Cardan here demonstrates, and applies in all its cases. The method is very general, and consists in forming three squares, thus: first, complete one side of the equation up to a square, by adding or subtracting some multiples or parts of some of its own terms on both sides, which it is always easy to do: 2d, supposing now the three terms of this square to be but one quantity, viz, the first term of another square to which this same side is to be completed, by annexing the square of a new and assumed indeterminate quantity, with double the product of the roots of both; which evidently forms the square of a binomial, consisting of the assumed indeterminate quantity and the root of the first square: 3d, the other side of the equation is then made to become the square of a binomial also, by supposing the product of its 1st and 3d terms to be equal to the square of half its 2d term; for it consists of only three terms, or three different denominations of the original unknown quantity: then this equality will determine the value of the assumed indeterminate quantity, by means of a cubic equation, and from it, that of the original ignota, by the equal roots of the 2d and 3d squares. Here we have a notable example of the use of assuming a new indeterminate quantity to introduce into an equation, long before Des Cartes was born, who made use of a like assumption for a similar purpose. And this method is very general, and is here applied to all forms of biquadratics, either having all their terms, or wanting some of them. To illustrate this rule, I shall here set down the process in one of his examples, which is this, $x^4 + 4x + 8 = 10x^2$. Now first subtract $2x^2 + 4x + 7$ from both sides, then the first becomes a square, viz, $x^2 - 2x^2 + 1$ or $(x^2 - 1)^2 = 8x^2 - 4x - 7$. Next assume the indeterminate y , and subtract $2y(x^2 - 1) - y^2$ from both sides, making the first side again a square, viz, $(x - 1)^2 - 2y(x - 1) + y^2$ or $(x^2 - 1 - y)^2 = (8 - 2y)x^2 - 4x + y^2 + 2y - 7$. Of this latter side, make the product of the 1st and 3d terms equal to the square of half the 2d term, that is, $(8 - 2y)(y^2 + 2y - 7) = 2^2$, which reduces to $y^3 + 30 = 2y^2 + 15y$; the positive roots of which are $y = 2$ or $\sqrt{15}$; and hence, using 2 for y , the equation of equal squares becomes $(x^2 - 1 - y)^2$ or $(x^2 - 3)^2 = 4x^2 - 4x + 1$, the roots of which give $x^2 - 3 = 2x - 1$; and hence $x^2 = 2x + 2$, or $x^2 + 2x = 4$; the two positive roots of which are $\sqrt{5} + 1$ and $\sqrt{5} - 1$, which are two of the values of x in the given equation $x^4 + 4x + 8 = 10x^2$. The other roots he leaves to be tried by the reader.

The 40th, or last, chap. is entitled, *On modes of general supposition relating to this art*; with some rules of an un-

usual kind; and estimatioes or roots of a nature different from the foregoing ones. Some of these are as follow: If $x^3 = ax^2 + c$, and $x - a = y$, and $x : y : : c : d$; then $is y^3 + ay^2 = d$.

Secondly, if $x^3 + ax^2 = c$, and $y^3 = ay^2 + c$,
then is $x + a : y - a : : y^2 : x^2$.

Thirdly, when $x^3 + c = ax^2$, the square will be taken away, by putting $x = y + \frac{1}{4}a$; and then the equation becomes $y^3 + c - 2(\frac{1}{4}a)^3 = \frac{1}{3}a^2y$.

Cardan adds some other remarks concerning the solutions of certain cases and questions, all evincing the accuracy of his skill, and the extent of his practice; he then concludes the book with a remark concerning a certain transformation of equations, which quite astonishes us, to find that the same person who, through the whole work, has shown such a profound and critical skill in the nature of equations, and the solution of problems, should yet be ignorant of one of the most obvious transmutations attending them, namely, increasing or diminishing the roots in any proportion. Cardan having observed that the form $x^3 = bx + c$ may be changed into another similar one, viz, $y^3 = \frac{b}{c}y + \sqrt{\frac{1}{c}}$, of which the coefficient of the term y is the quotient arising from the coefficient of x divided by the absolute number of the first equation; and that the absolute number of the 2d equation, is the root of the quotient of 1 divided by the said absolute number of the first; he then adds, that finding the estimatio or root of the one equation from that of the other is very difficult, *valde difficilis*.

It is matter of wonder that Cardan, among so many transmutations, should never think of substituting, instead of x in such equations, another positio or root, greater or less than the former in any indefinite proportion; that is, multiplied or divided by a given number; for this would have led him immediately to the same transformation as he makes above, and that by a way which would have shown the constant proportion between the two roots. Thus, instead of x in the given form $x^3 = bx + c$, substitute dy , and it becomes $d^3y^3 = bdy + c$; and this divided by d^3 becomes $y^3 = \frac{b}{d^2}y + \frac{c}{d^3}$; and here if d be taken = $\sqrt[c]{c}$, it becomes $y^3 = \frac{b}{c}y + \sqrt{\frac{1}{c}}$; the very transformation in question, and in which it is evident that $x = y\sqrt[c]{c}$, and $y = \sqrt[\frac{1}{c}]{c}$. Instead of this, Cardan gives the following strange way of finding the one root x from the other y , when this latter is by any means known; viz, Multiply the first given equation by $y^2x + 1$, then add $\frac{x^2}{4y^2}$ to both sides, and lastly extract the roots of both, which can always be done, as they will always be both of them squares; and the roots will give the value of x by a quadratic equation.

Thus, $x^3 = bx + c$ multiplied by $y^2x + 1$ gives $y^2x^4 + x^3 = by^2x^2 + (cy^2 + b)x + c$; add $\frac{x^2}{4y^2}$ then $y^2x^4 + x^3 + \frac{x^2}{4y^2} = by^2 + \frac{1}{4y^2}$. $x^2 + (b + cy^2)x + c$; and the roots are $y^2x^2 + \frac{x}{2y} = \sqrt{[(by^2 + \frac{1}{4y^2})x^2 + (b + cy^2)x + c]}$; and this 2d side of the equation, he says, will always have a root also. It is indeed true, that it will have an exact root; but the reason of it is not obvious, which is, because y is the root of the equation $y^3 = \frac{b}{c}y + \sqrt{\frac{1}{c}}$.

$\sqrt{\frac{1}{c}}$. Cardan has not shown the reason why this happens; but I apprehend he made it out in this manner, viz, similar to the way in which he forms the last square in the case of biquadratic equations, namely, by making the product of the 1st and 3d terms equal to the square of half the 2d term: thus, in the present case, it is $4c(by^2 + \frac{1}{4y^2})$

$= (b + cy^2)^2$, which reduces to $y^3 = \frac{b}{c}y + \sqrt{\frac{1}{c}}$ the equation in question. Therefore taking y the root of the equation $y^3 = \frac{b}{c}y + \sqrt{\frac{1}{c}}$, and substituting its value in the quantity $(by^2 + \frac{1}{4y^2})x^2 + (b + cy^2)x + c$, this becomes a complete square.

Of CARDAN'S *Libellus de Aliza Regula*. Subjoined to the above treatise on cubic equations, is this *Libellus de Aliza Regula*, or the algebraic logistics, in which the author treats of some of the more abstruse parts of arithmetic and algebra, especially cubic equations, with many more attempts on the irreducible case $x^3 = bx + c$. This book is divided into 60 chapters; but I shall only set down the titles of some few of them, whose contents require more particular notice.

Chap. 4. *De modo redigendi quantitates omnes, qua dicuntur latera prima, ex decimo Euclidis in compendium*. He treats here of all Euclid's irrational lines, as surd numbers, and performs various operations with them.

Chap. 5. *De consideratione binoniorum et recisorum, &c; ubi de astimatione capitulorum*. Contains various operations of multiplying compound numbers and surds.

Chap. 6. *De operationibus p: et m: (i. e. + and -) secundum communem usum*. Here it is shown that, in multiplication and division, plus always gives the same signs, and minus gives the contrary signs. So also in addition, every quantity retains its own sign; but in subtraction they change the signs. That the $\sqrt{+}$, or the square root of plus, is +; but the $\sqrt{-}$, or the square root of minus is nothing as to common use: (but of this below.) That $\sqrt[3]{-} = -$, as $\sqrt[3]{-8} = -2$. That a residual, composed of + and - may have a root also composed of + and -: so $\sqrt{(5 - \sqrt{24})} = \sqrt{3} - \sqrt{2}$. The rules for the signs in multiplication and division are illustrated by this example; to divide 8 by 2, + $\sqrt{6}$ or $\sqrt{6} + 2$. Take the two corresponding residuals $2 - \sqrt{6}$ and $\sqrt{6} - 2$, and by these multiply both the divisor and dividend; then the products are + and - respectively, and the quotients still both alike. Thus,

Divid.	Divis.	Divid.	Divis.
8	$\sqrt{6} + 2$	8	$2 + \sqrt{6}$
$\sqrt{6} - 2$	$\sqrt{6} - 2$	$2 - \sqrt{6}$	$2 - \sqrt{6}$
$\sqrt{384 - 16}$ divide + 2		$16 - \sqrt{384}$ div.	- 2
Quot. $\sqrt{96} - 8$.		Quot. $\sqrt{96} - 8$.	

And this method of performing division of compound surds, was fully taught before him, by Lucas de Burgo, namely, reducing the compound divisor to a simple quantity, by multiplying by the corresponding quantity, having the sign changed.

In chap. 11 and 18, and elsewhere, Cardan makes a general notation of a, b, c, d, e, f , for any indefinite quantities, and treats of them in a general way.

Chap. 2. *De contemplatione p: et m: (or + and -) et quod m: in m: facit p: et de causis horum justa veritatem*. Cardan here demonstrates geometrically that, in multipli-

cation and division, like signs give plus, and unlike signs give minus. And he illustrates this numerically, by squaring the quantity 8, or 6 + 2, or 10 - 2, which must all produce the same thing, namely, 64.

Among many of the chapters which treat of the irreducible case $x^3 = bx + c$, there is a peculiar kind of way given in chap. 31, which is entitled *De estimatione generali* $x^3 = bx + c$ solid vocata, et operationibus eius; in which he shows how to approximate to the root of that case, in a manner similar to approximating the square root and cube root of a number. The rule he uses for this purpose, is the 3d in chap. 25 of the last book, and it is this: Divide b into two parts, such that the sum of the products of each, multiplied by the square root of the other, may be equal to $\frac{1}{2}c$; then the sum of the roots of $\frac{9}{16}$ these parts is the *estimatio* or value of x required. So, of this equation $x^3 = 10x$ $\frac{3}{16}$ $\frac{1}{16}$ + 24; the two parts are 9 and 1, and their $3 + 9 = 12 = \frac{1}{2}c$, roots 3 and 1, and their sum $4 = x$, as $x = 3 + 1 = 4$. in the margin. Again, take $x^3 = 6x + 1$. Here he invents a new notation to express the root or radix, which he calls *solida*, viz., $x = \sqrt[3]{\text{solida}} 6$ in $\frac{1}{2}$, that is, the roots of the two parts of 6, so that each part multiplied by the root of the other, the two products may be $\frac{1}{2}$ or $\frac{1}{2}c$. Then to free this from fractions, and make the operation easier, multiply that root by some number, as suppose 4, that is, the square part 6 by the square of 4, and the solid part $\frac{1}{2}$ by the cube of 4; then $x = \sqrt[3]{\text{solida}} 96$ in 32. Now, by a few trials, it is found that the parts are

nearly $9\frac{5}{8}$ and $\frac{1}{8}$, which give too much,

or $9\frac{1}{8}$ and $\frac{7}{8}$, which give too little,

and thereof $9\frac{1}{2}$ and $\frac{1}{2}$ are still nearer. Divide both by 4 2 or 16, then $5\frac{1}{16}$ and $\frac{1}{16}$ are the quotients. And the sum of their roots, or $x = \sqrt[3]{5\frac{1}{16}} + \sqrt[3]{\frac{1}{16}}$ is nearly the value of the root x.

Chap. 42. *De dupliciti aequatione comparanda in capitulo cubi et numeri aquivalentium rebus.* Treats of the two positive roots of that case, neglecting the negative one; and showing, not only that the case has two such roots, but that the same number may be the common root of innumerable equations.

Chap. 57. *De tractatione estimationis generalis capitulo* $x^3 = bx + c$. Cardan here again resumes the consideration of the irreducible case, making ingenious observations upon it, but still without obtaining the root by a general rule. In this place also, as well as elsewhere, he shows how to form an equation in this case, that shall have a given binomial root, as suppose $\sqrt{m + n}$, where the equation will be $x^3 = (m + 3n^2)x + 2n(m - n^2)$, having $\sqrt{m + n}$ for one root, namely the positive root. From which it appears that he was well acquainted with the composition of cubic equations from given roots.

Chap. 59. *De ordine et exemplis in binominis secundo et quinto.* Contains a great many numeral forms of the same irreducible case $x^3 = bx + c$, with their roots; from which are derived these following cases, with many curious remarks. As, when

$$\begin{aligned} x^3 &= (c + 1)x + c, \text{ then } x = \sqrt[3]{(c + \frac{1}{2}) + \frac{1}{2}} \\ x^3 &= (\frac{1}{2}c + 4)x + c, \text{ then } x = \sqrt[3]{(\frac{1}{2}c + \frac{4}{3}) + \frac{1}{2}} \\ x^3 &= (\frac{1}{2}c + 9)x + c, \text{ then } x = \sqrt[3]{(\frac{1}{2}c + \frac{9}{4}) + \frac{1}{2}} \\ x^3 &= (\frac{1}{4}c + 16)x + c, \text{ then } x = \sqrt[3]{(\frac{1}{4}c + \frac{16}{9}) + \frac{1}{2}} \\ x^3 &= (\frac{1}{8}c + n^2)x + c, \text{ then } x = \sqrt[3]{(\frac{1}{8}c + \frac{n^2}{4}) + \frac{1}{2}}. \end{aligned}$$

Chap. 60. *Demonstratio generalis capituli cubi aequalis rebus et numero.* This demonstration of the irreducible case

is geometrical, like all the rest. Some more ingenious remarks are again added, as if he reluctantly finished the book, without perfectly overcoming the difficulty of the irreducible case. Cardan here also uses the letters a and b for any two indefinite numbers, in order to show the form and manner of the arithmetical operations: thus $\frac{a}{b}$ is the

fraction for their quotient, also $\sqrt{\frac{a}{b}}$ or $\frac{\sqrt{a}}{\sqrt{b}}$ the square root of that quotient, and $\sqrt[3]{\frac{a}{b}}$ or $\frac{\sqrt[3]{a}}{\sqrt[3]{b}}$ the cube root of it, &c.

Having considered the chief contents of Cardan's algebra, it will now be proper to sum them up, and set down a list of the improvements made by him, as collected from his writings.

And 1st, Tartalea having only communicated to him the rules for resolving these three cases of cubic equations, viz,

$x^3 + bx = c$, he thence raised a very large and complete work, laying down rules for all forms and $x^3 + c = bx$, varieties of cubic equations, having all their terms, or wanting any of them, and having all possible varieties of signs; demonstrating all these rules geometrically; and treating very fully of almost all kinds of transformations of equations, in a manner before unknown.

2d, It appears that he was well acquainted with all the roots of equations that are real, both positive and negative; or, as he calls them, true and fictitious; and that he made use of them both occasionally. He also showed that the even roots of positive quantities, are either positive or negative; that the odd roots of negative quantities, are real and negative; but that the even roots of them are impossible, or nothing as to common use. He was also acquainted with the

3d, Number and nature of the roots of an equation, and that partly from the signs of the terms, and partly from the magnitude and relation of the coefficients. He also knew,

4th, That the number of positive roots is equal to the number of changes of the signs of the terms.

5th, That the coefficient of the second term of the equation, is the difference between the positive and negative roots.

6th, That when the second term is wanting, the sum of the negative roots is equal to the sum of the positive roots.

7th, How to compose equations that shall have given roots.

8th, That, changing the signs of the even terms, changes the signs of all the roots.

9th, That the number of roots failed in pairs; or what we now call impossible roots were always in pairs.

10th, To change the equation from one form to another, by taking away any term out of it.

11th, To increase or diminish the roots by a given quantity. It appears also,

12th, That he had a rule for extracting the cube root of such binomials as admit of extraction.

13th, That he often used the literal notation $a, b, c, d, &c.$

14th, That he gave a rule for biquadratic equations, suiting all their cases; and that, in the investigation of that rule, he made use of an assumed indeterminate quantity, and afterwards found its value by the arbitrary assumption of a relation between the terms.

15th, That he applied algebra to the resolution of geometrical problems. And,

16th, That he was well acquainted with the difficulty of what is called the irreducible case, viz, $x^3 = bx + c$, upon which he spent a great deal of time, in attempting to overcome it. And though he did not fully succeed in this case, any more than other persons have done since, he nevertheless made many ingenious observations about it, laying down rules for many particular forms of it, and showing how to approximate very nearly to the root in all cases whatever.

Cardan died at Rome in the year 1575.

OF TARTALEA.

Nicholas Tartalea, or Tartaglia, of Brescia, was contemporary with Cardan, and was probably older than he was; but I do not know of any book of algebra published by him till the year 1546, the year after the date of Cardan's work on Cubic Equations, when he printed his *Quesiti et Inventioni diverse*, at Venice, where he resided as a public lecturer on mathematics. This work is dedicated to our king Henry the 8th of England, and consists of nine books, containing answers to various questions which had been proposed to him at different times, concerning mechanics, statics, hydrostatics, &c; but it is only the 9th, or last book, that we shall have occasion to take notice of in this place, as it contains all those questions which relate to arithmetic and algebra. These are all set down in chronological order, forming a pretty collection of questions and solutions on those subjects, with a short account of the occasion of each of them. Among these, the correspondence between him and Cardan forms a remarkable part, as we have here the history of the invention of the rules for cubic equations, which he communicated to Cardan, under the promise, and indeed oath, to keep them secret, on the 25th of March, 1539. But, notwithstanding his oath, finding that Cardan published them in 1545, as above related, it seems Tartalea published the correspondence between them, in revenge for his breach of faith; and it elsewhere appears, that many other sharp bickerings passed between them on the same account, which only ended with the death of Tartalea, in the year 1557.

It seems it was a common practice among the mathematicians, and others, of that time, as in most other times, to send to each other curious and difficult questions, as trials of skill; and to this circumstance it is that we owe the principal questions and discoveries in this collection, as well as many of the best discoveries of other authors. The collection now before us contains questions and solutions, with their dates, in a regular order, from the year 1521, and ending in 1541, in 42 dialogues, the last of which is with an English gentleman, namely, Mr. Richard Wentworth, who it seems was no mean mathematician, and who learned some algebra, &c, of Tartalea, while he resided at Venice. The questions at first are mostly very easy ones in arithmetic, but gradually become more difficult, and exercising simple and quadratic equations, with complex calculations of radical quantities: all showing that he was well skilled in the art of algebra as it then stood, and that he was very ingenious in applying it to the solution of questions. Tartalea made no alteration in the notation or forms of expression used by Lucas de Burgo, calling the first power of the unknown quantity, in his language, *cosa*, the second power *censa*, the third *cubo*, &c, and writing the names of all the operations in words at length,

without using any contractions, except the initial *R.* for root or radicality. So that the only thing remarkable in this collection, is the discovery of the rules for cubic equations, with the curious circumstances attending the same.

The first two of these were discovered by Tartalea in the year 1530, namely, for the two cases $x^3 + ax^2 = c$, and $x^3 = ax^2 + c$, as appears by Quest. 14 and 25 of this collection, on occasion of a question then proposed to him by one Zuanni de Tonini da Coi or Colle, John Hill, who kept a school at Brescia. And from the 25th question we learn, that he discovered the rules for the other two cases $x^3 + bx = c$, and $x^3 = bx + c$, on the 12th and 13th of February, 1535, at Venice, where he had come to reside the year before. And the occasion of it was this: There was then at Venice one Antonio Maria Fiore or Florido, who, by his own account, had received from his preceptor Scipio Farreo, about thirty years before, a general rule for resolving the case $x^3 + bx = c$. Being a captious man, and presuming on this discovery, Florido used to brave his contemporaries, and by his insults provoked Tartalea to enter into a wager with him, that each should propose to the other 30 different questions; and that he who soonest resolved those of his adversary, should win from him as many treats for himself and friends. These questions were to be proposed on a certain day at some weeks distance; and Tartalea made such good use of his time, that eight days before the time appointed for delivering the propositions, he discovered the rules both for the case $x^3 + bx = c$, and the case $x^3 = bx + c$. He therefore proposed several of his questions, so as to fall either on this latter case, or on the cases of the cube and square, expecting that his adversary would propose his in the former. And what he suspected fell out accordingly; the consequence of which was, that on the day of meeting Tartalea resolved all his adversary's questions in the space of two hours, without receiving one answer from Florido in return; to whom, however, Tartalea generously remitted the forfeit of the 30 treats won of him.

Question 31 first brings us acquainted with the correspondence between Tartalea and Cardan. This correspondence is very curious, and would well deserve to be given at full length in their own words, if it were not too long for this place. I may enlarge farther upon it under the article *Cubic Equations*; but must here be content with a brief abstract only. Cardan was then a respectable physician, and lecturer in mathematics, at Milan; who having nearly finished the printing of a large work on arithmetic, algebra, and geometry, and having heard of Tartalea's discoveries in cubic equations, he was very desirous of drawing those rules from him, that he might add them to his book before it was finished. For this purpose, he first applied to Tartalea, by means of a third person, a bookseller, whom he sent to him, in the beginning of the year 1539, with many flattering compliments, and offers of his services and friendship, &c, accompanied with some critical questions for him to resolve, according to the custom of the times. Tartalea however refused to disclose his rules to any one; as the knowledge of them gained him great reputation among all people, and gave him great advantage over his competitors for fame, who were commonly afraid of him on account of those very rules. He only sent Cardan therefore, at his request, a copy of the 30 questions which had been proposed to him in the contest with Florido.

Not to be rebuffed so easily, Cardan next applied, in

the most urgent manner, by letter, to Tartalea; which however procured from him only the solution of some other questions proposed by Cardan, and of a few of the questions that had been proposed to Florido, but none of their solutions. Finding he could not thus prevail, with all his fair promises, Cardan then fell upon another scheme. There was at Milan a certain Marquis dal Vasto, a great patron of Cardan, and, it was said, of learned men in general. Cardan conceived the idea of making use of the influence of this nobleman to draw Tartalea to Milan, hoping that then, by personal entreaties, he should succeed in drawing the long-concealed rules from him. Accordingly he wrote a second letter to Tartalea, much in the same strain with the former, strongly inviting him to come and spend a few days in his house at Milan, and representing that, having often commended him in the highest terms to the marquis, this nobleman desired much to see him; for which reason Cardan advised him, as a friend, to come to visit them at Milan, as it might be greatly to his interest, the marquis being very liberal and bountiful; and he besides gave Tartalea to understand, that it might be dangerous to offend such a man by refusing to come, who might, in that case, take offence, and do him some injury. This manoeuvre had the desired effect: Tartalea on this occasion laments to himself in these words, "By this I am reduced to a great dilemma; for if I go not to Milan, the marquis may take it amiss, and some evil may befall me on that account; I shall therefore go, though very unwillingly." When he arrived at Milan, however, the marquis was gone to Vigevano; and Tartalea was prevailed on to stay three days with Cardan, in expectation of the marquis returning; at the end of which time he set out from Milan, with a letter from Cardan, to go to Vigevano to that nobleman. While Tartalea was at Milan the three days, Cardan plied him by all possible means, to draw from him the rules for the cubic equations; and at length, just as Tartalea was about to depart from Milan, on the 25th of March, 1539, he was overcome by the most solemn protestations of secrecy that could be made. Cardan says, "I shall swear to you on the holy evangelists, and by the honour of a gentleman, not only never to publish your inventions, if you reveal them to me; but I also promise to you, and pledge my faith as a true Christian, to note them down in cyphers, so that after my death no other person may be able to understand them." To this Tartalea replies, "If I refuse to give credit to these assurances, I should deservedly be accounted utterly void of belief. But as I intend to ride to Vigevano, to see his excellency the marquis, as I have been here now these three days, and am weary of waiting so long; whenever I return therefore, I promise to show you the whole." Cardan answers, "Since you determine at any rate to go to Vigevano to the marquis, I shall give you a letter for his excellency, that he may know who you are. But now before you depart, I entreat you to show me the rule for the equations, as you have promised." "I am content," says Tartalea: "but you must know, that to be able on all occasions to remember such operations, I have brought the rule into rhyme; for if I had not used that precaution, I should often have forgot it; and though my rhymes are not very good, I do not value that, as it is sufficient that they serve to bring the rule to mind as often as I repeat them. I shall here write the rule with my own hand, that you may be sure I give you the discovery exactly."

These rude verses contain, in rather dark and enigmatical language, the rule for these three cases, viz.,
 $x^3 + bx = c,$ } which differ however only in the sign of
 $x^3 = bx + c,$ } one quantity, and the rule amounts to
 $x^3 + c = bx,$ } this: Find two numbers, x and y , such that their difference in the first case, and their sum in the 2d and 3d, may be equal to c the absolute number, and their product equal to the cube of $\frac{1}{3}$ of b the coefficient of the less power; then the difference of their cube roots will be equal to x in the first case, and the sum of their cube roots equal to x in the 2d and 3d cases: that is, taking $z - y = c$ in the first case, or $z + y = c$ in the 2d and 3d, and $zy = (\frac{1}{3}b)^3$; then $x = \sqrt[3]{z} - \sqrt[3]{y}$ in the first case, and $x = \sqrt[3]{z} + \sqrt[3]{y}$ in the other two. At parting, Tartalea, fails not again to remind Cardan of his obligation: "Now your excellency will remember not to break your promised faith, for if unhappily you should insert these rules either in the work you are now printing, or in any other, though you should even give them under my name, and as of my invention, I promise and swear that I shall immediately print another work that will not be very pleasing to you." "Doubt not," says Cardan, "but that I shall observe what I have promised: Go, and rest secure as to that point; and give this letter of mine to the marquis." It should seem, however, that Tartalea was much displeased at having suffered himself to be worried as it were out of his rules; for as soon as he quitted Milan, instead of going to wait upon the marquis, he turned his horse's head, and rode straight home to Venice, saying to himself, "By my faith I shall not go to Vigevano, but shall return to Venice, come of it what will."

After Tartalea's departure, it seems Cardan applied himself immediately to resolving some examples in the cubic equations by the new rules, but not succeeding in them; for indeed he had mistaken the words, as it was very easy to do in such bad verses, having mistaken $(\frac{1}{3}b)^3$ for $\frac{1}{2}b^3$, or the cube of $\frac{1}{3}$ of the coefficient, for $\frac{1}{3}$ of the cube of the coefficient; accordingly we find him writing to Tartalea in 14 days after the above, blaming him much for his abrupt departure without seeing the marquis, who was so liberal a prince, he said, and requesting Tartalea to resolve him the example $x^3 + 3x = 10$. This Tartalea did to his satisfaction, rightly guessing at the nature of his mistake; and concludes his answer with these emphatical words, "Remember your promise." On the 12th of May following, Cardan returns him a letter of thanks, together with a copy of his book, saying, "As to my work, just finished, to remove your suspicion, I send you a copy, but unbound, as it is yet too fresh to be beaten. But as to the doubt you express lest I may print your inventions, my faith, which I gave you with an oath, should satisfy you; for as to the finishing of my book, that could be no security, as I could always add to it whenever I please. But on account of the dignity of the thing, I excuse you for not relying on that which you ought to have done, namely, on the faith of a gentleman, instead of the finishing of a book, which might at any time be enlarged by the addition of new chapters; and there are besides a thousand other ways. But the security consists in this, that there is no greater treachery than to break one's faith, and to aggrieve those who have given us pleasure. And when you shall try me, you will find whether I be your friend or not, and whether I shall make an ungrateful return for your friendship, and the satisfaction you have given me."

It was within less than two months after this, however, that Tartalea received the alarming news of Cardan's showing some symptoms of breaking the faith he had so lately pledged to him; this was in a letter from a quondam pupil of his, in which he writes, "A friend of mine at Milan has written to me, that Dr. Cardano is composing another algebraical work, concerning some lately-discovered rules; hence I imagine they may be those same rules which you told me you had taught him; so that I fear he will deceive you." To which Tartalea replies, "I am heartily grieved at the news you inform me of, concerning Dr. Cardano of Milan; for if it be true, there can be no other rules but those I gave him; and therefore the proverb truly says, 'That which you wish not to be known, tell to nobody.' Pray endeavour to learn more of this matter, and inform me of it."

Tartalea, after this, kept on the reserve with Cardan, not answering several letters he sent him, till one written on the 4th of August the same year, 1539, complaining greatly of Tartalea's neglect of him, and farther requesting his assistance to clear up the difficulty of the irreducible case $x^3 = bx + c$, which Cardan had thus early been embarrassed with: he says that when $(\frac{1}{3}b)^3$ exceeds $(\frac{1}{2}c)^2$, the rule cannot be applied to the equation in hand, because of the square root of the negative quantities. On this occasion Tartalea turns the tables on Cardan, and plays his own game back upon him; for being aware of the above difficulty, and unable to overcome it himself, he wanted to try if Cardan could be encouraged to accomplish it, by pretending that the case might be done, though in another way. He says thus to himself, "I have a good mind to give no answer to this letter, no more than to the other two. However I will answer it, if it be but to let him know what I have been told of him. And as I perceive that a suspicion has arisen concerning the difficulty or obstacle in the rule for the case $x^3 = bx + c$, I have a mind to try if he can alter the data in hand, so as to remove the said obstacle, and to change the rule into another form, though I believe indeed that it cannot be done; however there is no harm in trying."—"M. Hieronime, I have received your letter, in which you write that you understand the rule for the case $x^3 = bx + c$; but that when $(\frac{1}{3}b)^3$ exceeds $(\frac{1}{2}c)^2$, you cannot resolve the equation by following the rule, and therefore you request me to give you the solution of this equation $x^3 = 9x + 10$. To which I reply, that you have not used a good method in that case, and that your whole process is entirely false. And as to resolving you the equation you have sent, I must say that I am very sorry that I have already given you so much as I have done; for I have been informed, by a credible person, that you are about to publish another algebraical work, and that you have been boasting through Milan of having discovered some new rules in algebra. But, take notice, that if you break your faith with me, I shall certainly keep my word with you, nay, I even assure you to do more than I promised." In Cardan's answer to this he says, "You have been misinformed as to my intention to publish more on algebra. But I suppose you have heard something about my work De Mysteriis Aeternitatis, which you take for some algebra I intend to publish. As to your repenting of having given me your rules, I am not to be moved from the faith I promised you for any thing you say." To this, and many other things contained in the same letter, Tartalea returned no answer, being still

suspicious of Cardan's intentions, and declining any more correspondence with him.

This however did not discourage C. for we find him writing again to T. on the 5th of January, 1540, to clear up another difficulty which had occurred in this business, namely, to extract the cube root of the binomials, of which the two parts of the rule always consisted, and for which purpose it seems C. had not yet found out a rule. On this occasion he informs T. that his quondam competitor Zuanne Colle had come to Milan, where, in some contests between them, Colle gave Cardan to understand that he had found out the rules for the two cases $x^3 + bx = c$, and $x^3 = bx + c$, and further that he had discovered a general rule for extracting the cube roots of all such binomials as can be extracted; and that, in particular, the cube root of $\sqrt{108} + 10$ is $\sqrt[3]{3} + 1$, and that of $\sqrt{108} - 10$ is $\sqrt[3]{3} - 1$, and consequently that $\sqrt[3]{(\sqrt{108} + 10)} - \sqrt[3]{(\sqrt{108} - 10)} = (\sqrt[3]{3} + 1) - (\sqrt[3]{3} - 1) = 2$. He then earnestly entreats T. to try to find out the rule, and the solution of certain other questions which had been proposed to him by Colle. By this letter T. is still more confirmed in his resolutions of silence; so that, without returning any answer, he only sets down among his own memorandums some curious remarks on the contents of the letter, and then concludes to himself, "Wherefore I do not choose to answer him again, as I have no more affection for him than for M. Zuanne, and therefore I shall leave the matter between them." Among those remarks he sets down a rule for extracting the cube root of such binomials as can be extracted, and that is done from either member of the binomial alone, thus: Take either term of the binomial, and divide it into two such parts that one of them may be a complete cube, and the other part exactly divisible by 3; then the cube root of the said cubic part will be one term of the required root, and the square root of the quotient arising from the division of $\frac{1}{3}$ of the 2d part by the cube root of the first, will be the other member of the root sought. This rule will be better understood in characters thus: let m be one member of the given binomial, whose cube root is sought; and let it be divided into the two parts a^3 and $3b$, so that $a^3 + 3b = m$; then is $a + \sqrt[3]{\frac{b}{a}}$ the cube root required, if it has one. Thus, in the quantity $\sqrt{108} + 10$, taking the term 10 for m , then 10 divides into 1 and 9, where $a^3 = 1$ or $a = 1$, and $3b = 9$ or $b = 3$: therefore $a + \sqrt[3]{\frac{b}{a}}$ becomes $1 + \sqrt[3]{3}$ for the cube root of $\sqrt{108} + 10$. And taking the other member $\sqrt{108}$, this divides into the two equal parts $\sqrt{27}$ and $\sqrt{27}$, making $a^3 = \sqrt{27}$, and $3b = \sqrt{27}$; hence $a = \sqrt[3]{3}$, and $b = \sqrt[3]{3}$ also; consequently $a + \sqrt[3]{\frac{b}{a}}$ is $\sqrt[3]{3} + \sqrt[3]{\frac{3}{3}}$ or $\sqrt[3]{3} + 1$ for the cube root of the binomial sought, the same as before. "And thus," he adds, "we may know whetherany proposed binomial or residual be a cube or a noncube; for if it be a cube, the same two terms for the root must arise from both the given terms separately; and if the two terms of the root cannot thus be brought to agree both ways, such binomial or residual will not be a cube." And thus ends the correspondence between them, at least for this time. But it seems they had still more violent disputes when C. in violation of his faith, so often pledged to the contrary, published his work on cubic equations 4 years afterwards, viz, in the year 1545, of which we have before given an

account, which disputes, it appears, continued till the death of Tartalea in the year 1557.

The last article in the volume contains a dialogue on some other forms of cubic equations, in the year 1541, between T. and Mr. Richard Wentworth, the English gentleman before-mentioned, who it seems had resided some time at Venice, on some public service from England, as T. in the dedication of the volume to Henry VIII, king of England, makes mention of him as "a gentleman of his sacred majesty." Mr. Wentworth had learned some mathematics of T. and being about to depart for England, requests T. to show him his newly discovered rules for cubic equations, as a farewell lesson; and it is worth while to note a few particulars in this conference, as they show pretty well the limited knowledge of T. at that time, as to the nature and roots of such equations. T. had before, it seems, showed Mr. W. the rules for the cases of the 3d and 1st powers, and now the latter desires him to do the same as to the three cases in which the 3d and 2d powers only are concerned. On this T. professes great gratitude to Mr. W. for many obligations, but desires to be excused from giving him the rules for these, because he says he intends soon to compose a new work on Arithmetic, Geometry, and Algebra, which he intends to dedicate to him, and in which he means to insert all his new discoveries. On Mr. W. urging him further, however, T. gives him the roots of some equations of that kind, as for instance:

If $x^3 + 6x^2 = 100$, then

$$x = \sqrt[3]{(42 + \sqrt{17000})} + \sqrt[3]{(42 - \sqrt{17000})} - 2.$$

If $x^3 + 9x^2 = 100$, then $x = \sqrt[3]{24} - 2$.

If $x^3 + 3x^2 = 2$, then $x = \sqrt[3]{-3} - 1$.

If $x^3 + 4 = 5x^2$, then $x = \sqrt[3]{8} + 2$.

If $x^3 + 6 = 7x^2$, then $x = \sqrt[3]{15} + 3$.

But he does not mention the rules for finding them.

In the course of the conversation T. tells him that "all such equations admit of two different answers, and perhaps more; and hence it follows that they have, or admit of, two different rules, and perhaps more, the one more difficult than the other." And on Mr. W. expressing his wonder at this circumstance of a plurality of roots, T. replies, "It is however very true, though hardly to be believed, and indeed if experience had not confirmed it, I should scarcely have believed it myself." He then commits a strange blunder in an example which he takes to illustrate this by, namely the equation $x^3 + 3x = 14$, which, he says, it is evident has the number 2 for one of its roots; and yet, he adds, "Whoever shall resolve the same equation by my rule, will find the value of x to be $\sqrt[3]{7 + \sqrt{50}} + \sqrt[3]{(7 - \sqrt{50})}$, which is proved to be a true root by substituting it in the equation for x . And therefore," continues he, "it is manifest that the case $x^3 + bx = c$ admits of two rules, namely, one (as in the above example) which ought to give the value of x rational, viz. 2, and the other is my rule, which gives the value of x irrational, as appears above; and there is reason to think that there may be such a rule as will give the value of $x = 2$, though our ancestors may not have found it out."—⁶ And these two different answers will be found not only in every equation of this form $x^3 + bx = c$, when the value of x happens to be rational, as in the example $x^3 + 3x = 14$ above, but the same will also happen in all the other five forms of cubic equations: and therefore there is reason to think that they also admit of two different rules; and by certain circumstances attending

some of them, I am almost certain that they admit of more than two rules, as, God willing, I shall soon demonstrate."

Now all this discourse shows a strange mixture of knowledge and ignorance. It is very probable that he had met with some equations which admit of a plurality of roots; indeed it was hardly possible for him to avoid it: but it seems he had no suspicion what the number of roots might be, nor that his reasoning in this instance was founded on an error of his own, mistaking the root $x = \sqrt[3]{(7 + \sqrt{50})} + \sqrt[3]{(7 - \sqrt{50})}$, of the equation $x^3 + 3x = 14$, for a different root from the number or root 2, when in reality it is the very same, as he might easily have found, if he had extracted the cube roots of the binomials by the rule which he himself had just given above for that purpose: for by that rule he would have found $\sqrt[3]{(7 + \sqrt{50})} = 1 + \sqrt[3]{2}$, and $\sqrt[3]{(7 - \sqrt{50})} = 1 - \sqrt[3]{2}$, and therefore their sum is $2 = x$, the same root as the other, which T. thought had been different. And besides this root 2, the equation in question, $x^3 + 3x = 14$, admits of no other real roots. Nor indeed does any equation of the same form, $x^3 + bx = c$, admit of more than one real root.

It seems also they had not yet discovered that all cases belong to the rules and forms for quadratic equations, which have only two powers in them, in which the exponent of the one is just double of the exponent of the other, as $x^{2a} + bx^a = c$; but some particular cases only of this sort they had as yet ventured to refer to quadratics, as the case $x^4 + bx^2 = c$. But, in the conclusion of this dialogue, T. informs W. of another case of this sort which he had accomplished, as a notable discovery, in these words: "I well remember," says he, "that in the year 1536, on the night of St. Martin, which was on a Saturday, meditating in bed when I could not sleep, I discovered the general rule for the case $x^6 + bx^3 = c$, and also for the other two, its accompanying cases, in the same night." And then he directs that they are to be resolved like quadratics, by completing the square, &c. And in these resolutions it is remarkable that he uses only the positive roots, without taking any notice of the negative ones.

Tartalea also published at Venice, in 1556, &c., a very large work, in folio, on Arithmetic, Geometry, and Algebra. This is a very complete and curious work on the first two branches; but that of Algebra is carried no farther than quadratic equations, called *book the first*, with which the work terminates. It is evidently incomplete, owing to the death of the author, which happened before this latter part of the work was printed, as appears by the dates, and by the prefaces. It appears also, from several parts of this work, that the author had many severe conflicts with Cardan and his friend Lewis Ferrari: and particularly, there was a public trial of skill between them, in the year 1547; in which it would seem that Tartalea had greatly the advantage, his questions mostly remaining unanswered by his antagonists.

OF MICHAEL STIFELIUS.

After the foregoing analysis of the works of the first algebraic writers in Italy, it will now be proper to consider those of their contemporaries in Germany; where it is remarkable that, excepting for the discoveries in cubic equations, the art was in a more advanced state, and of a form approaching nearer to that of our modern algebra; the states and circumstances indeed being so

different, that one would almost be led to suppose they had derived their knowledge of it from a different origin.

Here Stifelius and Scheubelius were writers of the same time with Cardan and Tartalea, and even before their discoveries, or publication, concerning the rules for cubic equations, Stifelius's Arithmetica Integra, being published at Norimberg in 1544, the year before Cardan's work on cubic equations, and is an excellent treatise, 'both on arithmetic and algebra.' The work is divided into three books, and is prefaced with an Introduction by the famous Melanchthon. The first book contains a complete and ample Treatise on Arithmetic, the second an Exposition of the 10th book of Euclid's Elements, and the third a Treatise on Algebra, being therefore properly the part with which we are at present concerned. In the dedication of this part, he ascribes the invention of algebra to Geber, an Arabic astronomer; and mentions besides, the authors Campanus, Christ. Rudolph, and Adam Ris, Risen, or Gigas, whose rules and examples he has chiefly given. In other parts of the book he speaks, and makes use also, of the works of Boetius, Campanus, Cardan (i. e. his Arithmetic published in 1539, before the work on cubic equations appeared), de Cusa, Euclid, Jordan, Milichius, Schonerus, and Stapulensis. So that he appears to have been very little acquainted indeed with any besides the German authors.

Chap. 1. *On the Rule of Algebra, and its parts.* Stifelius here describes the notation and marks of powers or denominations as he calls them, which marks for the several powers are thus:

1st, 2d, 3d, 4th, 5th, 6th, &c,
2¹, 3¹, 5¹, 33¹, ss¹, 3 ζ ¹, &c,

being formed from the initials of the barbarous way in which the Germans pronounced and wrote the Latin and Italic names of the powers, namely, res or cosa, zensus, cubo, zensi-zensus, sursolid, zensi-cubo, &c. And the cosa or first power 2^1 , he calls the radix or root, which is the first time that we meet with this word in the printed authors. He also here uses the signis or characters, + and -, for addition and subtraction, and the first of any that I know of: for in Italy they used none of these characters for a long time after. He has no mark however for equality, but makes use of the word itself.

Chap. 2. *On the Parts of the Rule of Geber or Algebra:* teaching the various reductions by addition, subtraction, multiplication, division, involution, and evolution, &c.

Chap. 3. *On the Algorithm of Cossic numbers;* teaching the usual operations of addition, subtraction, multiplication, division, involution, and extraction of roots, much the same as they are at present. Single terms, or powers, he calls simple quantities; but such as $1^3 + 1^2$, a composite or compound, and $2^2 - 8$ a defective one. In multiplication and division, he proves that like signs give +, and unlike signs -. He shows that the powers $1^1, 2^1, 3^1, \dots, \infty$, &c, form a geometrical progression from unity; and that the natural series of numbers 0, 1, 2, 3, &c, from 0, are the exponents of the cossic powers; and he, for the first time, expressly calls them exponents: thus,

Exponents, 0, 1, 2, 3, 4, 5, 6, &c.

Powers, 1, 2^1 , 3¹, 5¹, 33¹, ss¹, 3 ζ ¹, &c.

And he shows the use of the exponents, in multiplication, division, powers, and roots, as we do at present; viz, adding the exponents in multiplication, and subtracting them in division, &c. And these operations he demonstrates

from the nature of arithmetical and geometrical progressions. It is remarkable that these compound denominations of the powers are formed from the simple ones according to the *products* of the exponents; while those of Diophantus are formed according to the *sums* of them; thus the 6th power here is 3^6 or quadrato-cubi, but with Diophantus it is cubo-cubi; and so of others. Which is presumptive evidence that the Europeans had not taken their Algebra immediately from him, independent of other proofs.

Chap. 4. *On the extraction of the roots of cossic numbers.* He here treats of quadratic equations, which he resolves by completing the square, from Euclid ii, 4, &c. Also quadratics of the higher orders, showing how to resolve them in all cases, whatever the height may be, provided the exponents be but in arithmetical progression, as $2, 1, 0$ &c; where it is plain that he always counts 0 4, 2, 0 for the exponent of the unknown quantity in 6, 3, 0 the absolute term.

Chap. 5. *Of irrational cossic numbers, and of surd or negative numbers.* In this treatise of radicals or irrational numbers, he first uses the character $\sqrt{}$ to denote a root, and sets after it the mark of the power whose root is intended; as $\sqrt{3} 20$ for the square root of 20, and $\sqrt[3]{20}$ for the cube root of the same, and so on. He treats here also of negative numbers, or what he calls surd or fictitious, or numbers less than 0. On which he takes occasion to observe, that when a geometrical progression is continued downwards below 1, then the exponents of the terms, or the arithmetical progression, will go below 0 into negative numbers, and will yet be the true exponents of the former; as in these,

Expon. -3, -2, -1, 0, 1, 2, 3,
Pow. $\frac{1}{3}, \frac{1}{4}, \frac{1}{2}, 1, 2, 4, 8,$

And he gives examples to show that these negative exponents perform their office the same as the positive ones, in all the operations.

Chap. 6. *On the perfection of the Rule of Algebra, and of Secondary Roots.* In the reduction of equations, he uses a more general rule than those who had preceded him, who detailed the rule in a multitude of cases; instead of which, he directs to multiply or divide the two sides equally, to transpose the terms with + or -, and lastly to extract such root as may be denoted by the exponent of the highest power.

As to secondary roots, Cardan treated of a 2d *ignota* or unknown, which he called *quantitas*, and denoted it by the initial *q*, to distinguish it from the first. But here Stifelius, for distinction sake, and to prevent one root from being mistaken for others, assigns literal marks to all of them, as *A*, *B*, *C*, *D*, &c, and then performs all the usual operations with them, joining them together as we do now, except that he subjoins the initial of the power, instead of its numerical exponent: thus,

$3A$ into $9B$ makes $27AB$,
 33 into $4B$ makes $123B$,
 2ζ into $4A3$ makes $8\zeta A$,
 $1A$ squared makes $1A^2$,
 6 into $3C$ makes $18C$,
 $2A3$ into $5A$ makes $10A88$, &c, &c.,
 $8\zeta A^2$ divided by 4ζ makes $2A^2$, &c.,
The square root of $25A^2$ is $5A$, &c.,
Also $2A$ added to 2ζ makes $2\zeta + 2A$,
and $2A$ subtr. from 2ζ makes $2\zeta - 2A$.

And he shows how to use the same, in questions concerning several unknown numbers; where he puts a different character for each of them, as φ , Λ , B , C , &c.; he then makes out, from the conditions of the question, as many equations as there are characters; from these he finds the value of each letter, in terms of some one of the rest; and so, expelling them all but that one, reduces the whole to a final equation, as we do at present.

The remainder of the book is employed with the solutions of a great number of questions, to exercise all the rules and methods; some of which are geometrical ones.

From this account of the state of Algebra in Stifelius, it appears that the improvements made by himself, or other Germans, beyond those of the Italians, as contained in Cardan's book of 1539, were as follow:

1st. He introduced the characters $+$, $-$, $\sqrt{}$, for plus, minus, and root, or *radix*, as he calls it.

2d. The initials φ , Λ , B , &c., for the powers.

3d. He treated all the higher orders of quadratics by the same general rule.

4th. He introduced the numeral exponents of the powers, -3 , -2 , -1 , 0 , 1 , 2 , 3 , &c., both positive and negative, so far as integral numbers, but not fractional ones; calling them by the name *exponens*, exponent: and he taught the general uses of the exponents, in the several operations of powers, as we now use them, or the logarithms.

5th. And lastly, he used the general literal notation A , B , C , D , &c., for so many different unknown or general quantities.

OF SCHEUBELIUS.

John Scheubelius published several books on Arithmetic and Algebra. The one now before me, is entitled *Algebrae Compendiosa Facilisque Descriptio, quâ deponuntur magna Arithmetices miracula*. Authore Johanne Scheubelio Mathematicarum Professore in Academia Tubingensi. Parisiis 1552. But at the end of the book it is dated 1551. The work is most beautifully printed, and is very clear though succinct treatise; and both in the form and matter much resembles a modern printed book. He says that the writers ascribe this art to Diophantus, which is the first time that I find this Greek author mentioned by the modern algebraists; he further observes, that the Latins call it *Regula Rei et Census*, the rule of the thing and the square, or of the 1st and 2d power; and the Arabs, Algebra. His characters and operations are much the same as those of Stifelius, using the signs and characters $+$, $-$, $\sqrt{}$, and the powers φ , Λ , B , C , &c., where the character φ is used for 1 or unity, or a number, or the 0 power; prefixing also the numerical coefficients; thus $44\varphi^3 + 11\varphi + 31\varphi - 53\Lambda$. He uses also the exponents 0 , 1 , 2 , 3 , &c., of the powers, the same way as Stifelius, before him. He performs the algebraical calculations, first in integers, and then in fractions, much the same as we do at present. Then of equations, which he says may be of infinite degrees, though he treats only of two, namely the first and second orders, or what we call simple and quadratic equations, in the usual way, taking however only the positive roots of these; and advertizing to all the higher orders of quadratics, namely,

x^4 , ax^3 , b ; and x^6 , ax^5 , b ; and x^8 , ax^7 , b ; &c.

Next follows a tract on surds, both simple and compound, quadratic, cubic, binomial, and residual. Here he first marks the notation, observing that the root is ci-

ther denoted by the initial of the word, or, after some authors, by the mark $\sqrt{}$; viz, the sq. root $\sqrt{}$; the cube root $\sqrt[3]{}$; and the 4th root, or root of the root thus $\sqrt[4]{}$; which latter method he mostly uses. He then gives the Arithmetic of surds, in multiplication, division, addition, and subtraction. In these last two rules he squares the sum or difference of the surds, and then sets the root to the whole compound, which he calls *radix collecti*, what Cardan calls *radix universalis*. Thus $\sqrt{12 \pm \sqrt{20}}$ is ral. $32 \pm \sqrt{960}$. But when the terms will reduce to a common surd, he then unites them into one number; as $\sqrt{27} + \sqrt{12}$ is equal $\sqrt{75}$. Also of cubic surds, and 4th roots. In binomial and residual surds, he remarks the different kinds of them which answer to the several irrational lines in the 10th book of Euclid's elements; and then gives this general rule for extracting the root of any binomial or residual $a \pm b$, where one or both parts are surds, and a the greater quantity, namely, that the square root of it is $\sqrt{\frac{a^2 + \sqrt{(a^2 - b^2)}}{2}} \pm \sqrt{\frac{a - \sqrt{(a^2 - b^2)}}{2}}$, which he illustrates by many examples. This rule will only succeed however, so as to come out in simple terms, in certain cases, namely, either when $a^2 - b^2$ is a square, or when a and $\sqrt{(a^2 - b^2)}$ will reduce to a common surd, and unite: in all other cases the root is in two compound surds, instead of one. He gives also another rule, which comes however to the same thing as the former, though by the words of them they seem to be different.

Scheubelius wrote much about the time of Cardan and Stifelius. And as he takes no notice of cubic equations, it is probable he had neither seen nor heard any thing about them; which might very well happen, the one living in Italy, and the other in Germany. And besides, I know not if this be the first edition of Scheubel's book: it is rather likely it is not, as it is printed at Paris, and he himself was professor of mathematics at Tubingen in Germany.

ROBERT RECORDE.

To this ingenious man we are indebted for the first treatise on algebra, then named the Cossic Art, in the English language; but his meritorious labours, like those of the greatest benefactors of mankind, appear to have been ill requited, since, after removing to the capital, he died under confinement for debt in the Fleet-prison. In his book on Arithmetic he is styled "teacher of mathematics and practitioner in physic at Cambridge." It was for many ages the custom to unite the title as well as the practice of medicine with those of chemistry, alchymy, mathematics, and astrology, by the Moors, and after them by the Europeans, and is still continued among the almanac-makers. And it is remarkable, that as the Moors were not less famed in Europe for their skill in medicine, than their dexterity in calculation, the term Physician and Algebrist appear at first to have been regarded as almost synonymous. Thus, it is curious to remark, that in the celebrated romance of Don Quixote, published about this time, the bachelor Samson Carrasco, who in his encounter with the knight was thrown from his horse, and had his ribs broken, sent in quest of an *Algebrista* to heal his bruises.

The first part of his Arithmetic was published in 1552; and the second part in 1557, under the title of "The Whetstone of Witte, which is the seconde part of Arithmetike: containing the Extraction of Rootes: The Cossiske Practise, with the Rule of Equation: and the Workes of

Surde Numbers." The work is in dialogue between the master and scholar; and is nearly after the manner of the Germans, Stifelius and Scheubelius, but especially the latter, whom he often quotes, and takes examples from. The chief parts of the work are, 1st, The properties of abstract and figurate numbers. 2d, The extraction of the square and cube roots, much the same as at present. Here, when the number is not an exact power, but having some remainder over, he either continues the root into decimals as far as he pleases, by adding to the remainders always periods of ciphers; or else makes a vulgar fraction for the remaining part of the root, by taking the remainder for the numerator, and double the root for the denominator, in the square root; but in the cube root he takes, for the denominator, either the triple square of the root, which is Cardan's rule, or the triple square and triple root, with one more, which is Scheubel's rule. 3d, Of Algebra, or "Cossike Numbers." He uses the notations of powers with their exponents the same as Stifel, with all the operations in simple and compound quantities, or integers and fractions. And he gives also many examples of extracting the roots of compound algebraic quantities, even when the roots are from two to six terms, in imitation of the same process in numbers, just as we do at present; which is the first instance of this kind that I have observed. As of this quantity:

Square Root.

$$253\sqrt{1} + 80\sqrt{3} - 26\sqrt{3} - 144\sqrt{1} + 81\sqrt{3}(5\sqrt{1} + 8\sqrt{3} - 9\sqrt{2}).$$

4th, "The Rule of Equation, commonly called Algebra's Rule." He here, first of any, introduces the character $=$, for brevity sake. His words are, "And to avoid the tedious repetition of these woordes: \therefore is equalle to: I will sette as I doe often in woorke use, a paire of parallelles, or genowe lines of one lengthe, thus: $=$, bicause noe 2 thynges can be moare equalle." He gives the rules for simple and quadratic equations, with many examples. He gives also some examples in higher compound equations, with a root for each of them, but gives no rule how to find it. 5th, "Of Surde Numbers." This is a very ample treatise on surds, both simple and compound, and surds of various degrees, as square, cubic, and biquadratic, marking the roots in Scheubel's manner, thus: $\sqrt{}$, $\sqrt[3]{}$, $\sqrt[4]{}$. He here uses the names bimedial, binomial, and residual; but says they have been used by others before him, and indeed by Lucas de Burgo, as in cart. 120, edit. 1494.—Hence it appears that the things which chiefly are new in this author, are these two, viz.,

1. The extraction of the roots of compound algebraic quantities.

2. The use of the sign of equality, or $=$.

OF PELETARIUS.

The first edition of this author's algebra was printed in 4to at Paris, in 1558, under this title, *Jocobi Peletarii Cenoniani, de occulta parte Numerorum, quam Algebra vocant. Lib. duo.*

In the preface he speaks of the supposed authors of Algebra, namely Geber, Mahomet the son of Moses, an Arabian, and Diophantus. But he thinks the art older, and mentions some of his contemporary writers, or a very little before him, as Cardan, Stifel, Scheubel, Chr. Januarius; and a little earlier again, Lucas Paciolus of Florence, and Stephen Villafrancus a Gaul.

Of the two books, into which the work is divided, the first is on rational, and the second on irrational or surd

quantities; each being divided into many chapters. It will be sufficient to mention only the principal articles.

He calls the series of powers *numeri creati*, or derived numbers, or also radicals, because they are all raised from one root or *radix*. He names them thus, radix, quadratus, cubus, quadrato-quadratus, or biquadratus, supersolidus, quadrato-cubus, &c.; and marks them thus \mathbb{R} , q , \mathbb{C} , qq , ss , $g\mathbb{C}$, bss , &c. Of these he gives the following series in numbers, having the common ratio 2, with their marks set over them, and the exponents set over these again, in an arithmetical series, beginning at 0, thus:

0	1	2	3	4	5	6	7	8
	\mathbb{R}	q	\mathbb{C}	qq	ss	$g\mathbb{C}$	bss	ggg
1	2	4	8	16	32	64	128	256 &c.

And he shows the use of the exponents, the same as Stifel and Scheubel; like them also he prefixes coefficients to quantities of all kinds, as also the radical $\sqrt{}$. But he does not follow them in the use of the signs $+$ and $-$, but employs the initials p and m for the same purpose. After the operations of addition, &c., he performs involution, and evolution also, much the same way as at present: thus, in powers, raise the coefficient to the power required, and multiply the exponent, or sign, as he calls it, by 2, or 3, or 4, &c., for the 2d, 3d, 4th, &c., power; and the reverse for extraction: and hence he observes, if the number or coefficient will not exactly extract, or the sign do not exactly divide, the quantity is a surd.

After the operations of compound quantities, and fractions, and reduction of equations, namely simple and quadratic equations, as usual, in chap. 16, *De Inveniendis generatim Radicibus Denominatorum*, he gives a method of finding the roots of equations among the divisors of the absolute number, when the root is rational, whether it be integral or fractional; for then, he observes the root always lies hid in that number, and is some one of its divisors. This is exemplified in several instances, both of quadratic and cubic equations, and both for integral and fractional roots. And he here observes, that he knows not of any person who has yet given general rules for the solution of cubic equations; which shows that when he wrote this book, either Cardan's last book was not published, or else it had not yet come to his knowledge.

Chap. 17 contains, in a few words, directions for bringing questions to equations, and for reducing these. He here observes, that some authors call the unknown number *res*, and others the *positio*; but that he calls it *radix*, or root, and marks it thus \mathbb{R} : hence the term, root of an equation. But it was before called *radix* by Stifelius.

Chap. 21 & seq. treat of secondary roots, or a plurality of roots, denoted by a , b , c , &c., after Stifelius.

The 2d book contains the like operations in surds, or irrational numbers, and is a very complete work on this subject indeed. He treats first of simple or single surds, then of binomial surds, and lastly of trinomial surds. He gives here the same rule for extracting the root of a binomial and residual as Scheubelius, viz., $\sqrt{(a \pm b)} = \sqrt{\frac{a + \sqrt{(a^2 - b^2)}}{2}} \pm \sqrt{\frac{a - \sqrt{(a^2 - b^2)}}{2}}$. In dividing by a binomial or residual, he proceeds as all others before him had done, namely, reducing the divisor to a simple quantity, by multiplying it by the same two terms with the sign of one of them changed, that is by the binomial if it be a residual, or by the same residual if it be a bino-

mial; and multiplying the dividend by the same thing: thus $\frac{3}{\sqrt{5}-2} = \frac{3}{\sqrt{5}-2} \times \frac{\sqrt{5}+2}{\sqrt{5}+2} = \frac{3\sqrt{5}+6}{5-4} = 3\sqrt{5}+6$. And, in imitation of this method, in division by trinomial surds, he directs to reduce the trinomial divisor first to a binomial or residual, by multiplying it by the same trinomial with the sign of one term changed, and then to reduce this binomial or residual to a simple nominal as above; observing to multiply the dividend by the same quantities as the divisor. Thus, if the divisor be $4+\sqrt{2}-\sqrt{3}$; multiplying this by $4+\sqrt{2}+\sqrt{3}$, the product is $15+8\sqrt{2}$; then this binomial multiplied by the residual $15-8\sqrt{2}$, gives $225-128$ or 97 for the simple divisor; and the dividend, whatever it is, must also be multiplied by the two $4+\sqrt{2}+\sqrt{3}$ and $15-8\sqrt{2}$. Or in general if the divisor be $a+\sqrt{b}-\sqrt{c}$; multiply it by $a+\sqrt{b}+\sqrt{c}$; which gives $(a+\sqrt{b})^2-c=a^2+b-c+2a\sqrt{b}$; then multiply this by $-a^2+b-c-2a\sqrt{b}$, and it gives $(a^2+b-c)^2-4a^2b$, which will be rational, and will all collect into one single term. But Tartalea must have been in possession of some such rule as this, as one of the questions he proposed to Flordio was of this nature, namely to find such a quantity as multiplied by a given trinomial surd, shall make it rational: and it appears, from what is done above, that, the given trinomial being $a+\sqrt{b}-\sqrt{c}$, the answer will be $(a+\sqrt{b}+\sqrt{c}) \times (a^2+b-c+2\sqrt{b})$.

Chap. 24 shows the composition of a cube of a binomial or residual, and thence remarks on the root of the case or equation $1 \pm p 3 \sqrt{2}$ equal to 10, which he seems to know something about, though he had not Cardan's rules.

Chap. 30, which is the last, treats of certain precepts relating to square and cubic numbers, with a table of such squares and cubes from all numbers to 140; also showing how to compute them both, by adding always their differences.

He then concludes with remarking that there are many curious properties of these numbers, one of which is this, that the sum of any number of the cubes, taken from the beginning, always makes a square number, the root of which is the sum of the roots of the cubes; so that the series of squares so formed, have for their roots 1, 3, 6, 10, 15, 21, &c, whose diff. are the natural nos 1, 2, 3, 4, 5, 6, &c. Namely, $1^3=1^2$; $1^3+2^3=3^2$; $1^3+2^3+3^3=6^2$, &c. Or in general, $1^3+2^3+3^3+\dots-n^3=(1+2+3+\dots-n)^2=\frac{1}{4}n(n+1)^2=\frac{1}{4}\pi^2(n+1)^2$.

This work of Peletarius is a very ingenious and masterly composition, treating in an able manner of the several parts of the subject then known, excepting the cubic equations. But his real discoveries, or improvements, may be reduced to these three, viz.

1st. That the root of an equation is one of the divisors of the absolute term.

2d. He taught how to reduce trinomials to simple terms, by multiplying them by compound factors.

3d. He taught curious precepts and properties concerning square and cube numbers, and the method of constructing a series of each by addition only, namely by adding successively their several orders of differences.

PETER RAMUS.

Peter Ramus wrote his arithmetic and algebra about the year 1560. His notation of the powers is thus, l , q , c , bq , being the initials of latus, quadratus, cubus, biqua-

datus. He treats only of simple and quadratic equations. And the only thing remarkable in his work, is the first article, on the name and invention of Algebra, which we have noticed at the beginning of this history.

OF PEDRO NUNEZ OR NUÑEZ, OR IN LATIN NONIUS.

Peter Nunez or Nonius, was a very ingenious and eminent physician and mathematician, for the time in which he lived. He was born in 1497, at Alcazar in Portugal, and died in 1577, at 80 years of age. He was professor of mathematics in the university of Coimbra, where he published several ingenious and useful pieces on different branches of the mathematics, as may be seen by the account of his life given in the 2d vol. of this Dictionary; but it is only with his Algebra that our business is at present.

This work he had composed in Portuguese, but translated it into the Castilian tongue, when he resolved on making it public, which he thought would render his book more useful, as this language was more generally known than the former. The dedication, to his former pupil, prince Henry, was dated from Lisbon, Dec. 1, 1564; and the work contains 341 leaves, equal to 682 closely printed pages, in the Antwerp edition of 1567, in 8vo; the folios being numbered only on one side.

The work is very methodically and plainly treated; being divided into regular and distinct chapters or sections; leading the reader gradually through the several operations of computation, in integers and fractions, in powers and roots, in surds and in proportions, &c. The rules for dignities or powers are given; and these he denominates from the product of their indices; thus, for the powers of 2, with their names, and denominations under them:

2	4	8	16	32	64
Co. Ce. Cu.	Ce. Ce.	Re. p.	Ce. Cu.	or Cu. Ce. &c.	

1 2 3 4 5 6

where the 6th denomination is called Ce. Cu. or Cu. Ce. that is Censo-Cubo or Cubo-Censo, meaning the square cubed or the cube squared, the index 6 denoted by 2×3 , the product of the indices of the powers; after the manner of the former European authors, Lucas de Burgo, Tartalea, and Cardan. And exactly after the manner of these also is his practice in every other part, with little or no variation, as far as he goes, which is to quadratic equations; without treating on cubics, further than giving some account of the dispute between Tartalea and Cardan concerning their invention; and that in such a manner as shows he did not very well understand them. Like those authors are his names and rules for Raizes, roots or radicals, which he sometimes calls Sorda, surds. In their marks or signs also; as R for root; \bar{p} for +; \bar{m} for minus; $R. u$. for root universal, instead of the vinculi used by the moderns; also L for ligature or composition, such as $L. R. 9$ with $R. 4$, composed of 3 which is $R. 9$, and of 2 which is $R. 4$, making 5. He places likewise the name of the root after the R ; as $R. cu. 25. \bar{m}. R. cu. 15. \bar{p}. R. cu. 9$; that is, $\sqrt[3]{25}-\sqrt[3]{15}+\sqrt[3]{9}$.

After all the usual preparatory rules, Nunez then treats of equations, simple and quadratic, in the common way, and giving geometrical demonstrations of the rules, as had been done before. He then applies these equations in the solution of a great number of examples, of questions or problems, first in numbers or arithmetic, and then in geometrical problems or figures; in which he proceeds orderly through the several kinds; as squares, rectangles,

triangles, rhombs, rhomboids, trapeziums, pentagons, &c: all which he calls by the same names as at present. The content of a figure too he calls its Area, as De Burgo did before him; and after the same author also he gives the geometrical demonstration of the common rule for finding the area of a triangle from the three sides given. He treats on the inscription of circles and squares in triangles of various kinds; and the division of triangles into several parts in different ways.

In an address to his readers, at the end of the book, Nunez informs them what are the authors whose books, on his subject, are to be found in Spain, which consist only of De Burgo, Tartalea, and Cardan; stating his ideas on the merits of their works, with critical remarks on many parts of them, in which he more particularly approves of those of Tartalea. Upon the whole, the merit of Nunez, in this art, consists chiefly, or wholly, in having given a very neat and orderly treatise on it, after the manner of those authors; but without having made any improvements or inventions of his own, in the art.

On this occasion it is very remarkable to observe, that Nunez appears not to have been at all acquainted with any of the Germanic authors, several of whom were contemporaries of Tartalea and Cardan, and who treated the subject in a better manner, in some respects, than these did. Another thing may be here noticed on this occasion, as remarkable; not only that we have never heard of any other early writers on this subject, in Spain or Portugal; but that we have never heard of writings on it by the Moors, who occupied great part of that peninsula during several centuries, by whom we have always been taught to believe that the arts of arithmetic and algebra were brought into that country.—Had that people left any such works in the country, would not some of them have been found in some of the great cities or the universities, or could they yet be in existence there?—Or could the people have carried all their books away with them when they were expelled from the country?

BOMBELLIS.

Raphael Bombelli's Algebra was published at Bologna in the year 1572, in the Italian language. In a short, but neat, introduction, he first adverts, in a few words, to the great excellence and usefulness of arithmetic and algebra. He then laments that it had hitherto been treated in so imperfect and irregular a way; and declares it his intention to remedy all defects, and to make the science and practice of it as easy and perfect as may be. And for this purpose he first resolved to procure and study all the former authors. He then mentions several of these, with a short history or character of them; as Mahomet the son of Moses, an Arabian; Leonard Pisano; Lucas de Burgo, the first printed author in Europe; Oroncius; Scribelius; Boglione Francesi; Stifelius in Germany; a certain Spaniard, perhaps meaning Nunez or Nouius; and lastly Cardan, Ferrari, and Tartalea; with some others since, whose names he omits. He then adds a curious paragraph concerning Diophantus: he says that some years since there had been found, in the Vatican library, a Greek work on this art, composed by a certain Diophantus, of Alexandria, a Greek author, who lived in the time of Antoninus Pius; which work having been shown to him by Mr. Antonio Maria Pazzi Reggiano, public lecturer on mathematics at Rome; and finding it to be a good work, these two formed the design of giving it to the

world; and he says that they had already translated five books, of the seven which were then extant, being as yet hindered by other avocations from completing the work. He then adds the following strange circumstance, viz., that they had found that in the said work the Indian authors are often cited; by which he learned that this science was known among the Indians before the Arabians had it: a paragraph the more remarkable as I have never understood that any other person could ever find, in Diophantus, any reference to Indian writers: and I have examined his work with some attention, for that purpose. Probably the copy which Bombelli saw, contained marginal remarks by Plinudes, or some other scholiast, making mention of the Indian works on the science, or some such remarks; which might be mistaken for part of the text of Diophantus.

Bombelli's work is divided into three books. In the first, are laid down the definitions and operations of powers and roots, with various kinds of radicals, simple and compound, binomial, residual, &c; mostly after the rules and manner of former writers, excepting in some few instances, which I shall here take notice of. And first of his rule for the cube root of binomials or residuals, which, for the sake of brevity, may be expressed in modern notation as follows: let $\sqrt[3]{b+a}$ be the binomial, the term $\sqrt[3]{b}$ being greater than a ; then the rule for the cube root of $\sqrt[3]{b+a}$ comes to this, $p - q + \sqrt[3]{[(p-q)^2 + \sqrt[3]{(b-a^2)}]}$; where $p = \sqrt[3]{(\sqrt[3]{\frac{a^2}{64} + \frac{b-a^2}{64}} + \frac{a}{8})}$, and $q = \sqrt[3]{\sqrt{(\frac{a^2}{64} + \frac{b-a^2}{64})} - \frac{a}{8}}$. Which is a rule that can be of little or no use. For in the first place, $(p-q)^2 + \sqrt[3]{(b-a^2)}$ is the same as $(p+q)^2$; and p or $\sqrt[3]{(\sqrt[3]{\frac{a^2}{64} + \frac{b-a^2}{64}} + \frac{a}{8})}$ is $= \sqrt[3]{(\sqrt[3]{\frac{b}{64}} + \frac{a}{8})} = \sqrt[3]{\frac{\sqrt[3]{b+a}}{8}} = \frac{1}{2}\sqrt[3]{(\sqrt[3]{b} + a)}$; therefore the whole $p - q + \sqrt[3]{(p-q)^2 + \sqrt[3]{(b-a^2)}}$ reduces to $p - q + p + q = 2p = 2 \times \frac{1}{2}\sqrt[3]{(\sqrt[3]{b} + a)} = \sqrt[3]{(\sqrt[3]{b} + a)}$, the original quantity first proposed.

The next thing remarkable in this 1st book, is his method for the square roots of negative quantities, and his rule for the cube roots of such imaginary binomials as arise from the irreducible case in cubic equations. His words, translated, are these: "I have found another sort of cubic root, very different from the former, which arises from the case of the cube equal to the first power and a number, when the cube of the $\frac{1}{2}d$ part of the (coef. of the) 1st power, is greater than the square of half the absolute number, which kind of square root hath, in its algorism, names and operations different from the others; for in that case, the excess cannot be called either plus or minus; I therefore call it *plus of minus* when it is to be added, and *minus of plus* when it is to be subtracted." He then gives a set of rules for the signs when such roots are multiplied, and illustrates them by a great many examples. His rule for the cube roots of such binomials, viz., such as $a + \sqrt[3]{-b}$, is this: First find $\sqrt[3]{(a^2 + b)}$; then, by trials search out a number c , and a sq. root, $\sqrt[3]{d}$, such, that the sum of their squares $c^2 + d$ may be $= \sqrt[3]{(a^2 + b)}$, and also $c^2 - 3cd = a$; then shall $c + \sqrt[3]{-b}$ be $= \sqrt[3]{(a + \sqrt[3]{-b})}$ sought. Thus, to extract the cube root of $2 + \sqrt[3]{-121}$: here $\sqrt[3]{(a^2 + b)} = \sqrt[3]{125} = 5$; then taking $c=2$, and $d=1$, it is $c^2 + d = 5 = \sqrt[3]{(a^2 + b)}$, and $c^2 - 3cd = 8 - 6 = 2 = a$, as it ought; and therefore $2 + \sqrt[3]{-121}$ is $=$ the cube root of $2 + \sqrt[3]{-121}$, as required.

The notation in this book, is the initial *R* for root, with *q* or *c*, &c, after it, for quadrate or cubic, &c root. Also *p* for *plus*, and *m* for *minus*.

In the 2d book, Bombelli treats of the algorism with unknown quantities, and the resolution of equations. He first gives the definitions and characters of the unknown quantity and its powers; in which he deviates from the former authors, but professes to imitate Diophantus. He calls the unknown quantity *tanto*, and marks it

thus - - - - $\frac{1}{2}$,
Its square or 2d power *potenza*, $\frac{1}{2}$,
Its cube - - - - *cubo*, $\frac{1}{3}$,

and the higher names are compounded of these, and marked $\frac{4}{5}$, $\frac{5}{6}$, $\frac{6}{7}$, &c; so that he denotes all the powers by their exponents set over the common character $\frac{1}{n}$. And all these powers he calls by the general name *dignita*, dignity. He then performs all the algorism of these powers, by means of their exponents, as we do at present, viz, adding them in multiplication, subtracting in division, multiplying them by the index in involution, and dividing by the same in evolution.

In equations he goes regularly through all the cases, and varieties of the signs and terms; first all the simple or single powers, and then all the compound cases; demonstrating the rules geometrically, and illustrating them by many examples.

In compound quadratics, he gives two rules: the first is by freeing the *potenza* or square from its coefficient by division, and then completing the square, &c, in the usual way: and the 2d rule, when the first term has its coefficient, may be thus expressed; if $ax^2 + bx = c$, then $x = \sqrt{\left(ax + \frac{1}{4}b^2\right) - \frac{1}{2}b}$, being a way that was practised by the In-

dians. He takes only the positive root or roots; and in the case $ax^2 + c = bx$, which has two, he observes that the nature of the problem must show which of the two is the proper one.

In the cubic equations, he gives the rules and transformations, &c, after the manner of Cardan; remarking that some of the cases have only one root, but others two or three, of which some are true, and others false or negative. And in one place he says that by means of the case $x^3 = bx + c$, he *trisects or divides an angle into three equal parts*.

When he arrives at biquadratic equations, and particularly to this case $x^4 + ax = b$, he says, "Since I have seen Diophantus's work, I have always been of opinion that his chief intention was to come to this equation, because I observe he labours at finding always square numbers, and such, that adding some number to them, may make squares; and I believe that the six books, which are lost, may treat of this equation, &c."—"But Lewis Ferrari," he adds, "of this city, also laboured in this way, and found out a rule for such cases, which was a very fine invention, and therefore I shall here treat of it the best I can." This he accordingly does, in all the cases of biquadratics, both with respect to the number of terms in the equation, and the signs of the terms, except I think this most general case only $rx - qx^2 + px^3 - x^4 = s$; fully applying Ferrari's method in all cases. Which concludes the 2d book.

The 3d book consists only of the resolution of near 300 practical questions, as exercises in all the rules and equations, many of which are taken from other authors, especially from the first five books of Diophantus.

Upon the whole it appears, that this is a plain, explicit, and very orderly treatise on algebra, in which are very well explained the rules and methods of former writers. But Bombelli does not produce much of improvement or invention of his own, except his notation, which varies from others, and is by means of one general character, with the numeral indices of Stifelius. He also first remarks that angles are trisected by a cubic equation.

GULIELMI GOSALINI, &c.

De Arte Magna, seu de Occulta Parte Numerorum qua et Algebra et Almucabala vulgo dicitur, libri quatuor. In quibus explicantur aequationes Diophanti, Regula Quantitatis Simplicis, et Quantitatis Surda.—Paris, 1577, in small 8vo, 86 leaves, numbered only on one side.

In the dedication, this author notices the term *Cossic Numbers*; and mentions many of the former writers; as, Diophantus, Forcadel, Scheubel, Peletare, Stifel, Cardan, Lucas, Villafranc, Nunez, and Tartaglia, whose work he says he had translated and published in French. The present work seems meant as an elementary book of instruction, being regularly divided into chapters, and treated methodically, though not deeply. The chapters are, on quantity, on the methods of numeration, on the object of algebra, on the names of numbers with respect to their powers, which are thus denoted: *l* the latus or number, *q* the quadrant or square, *c* the cube, *qq* the square-squared or 4th power, *rr* the relatus-primus or 5th power (Called by Diophantus quadratocubus), *rs* the relatus-secundus or 7th power, *qqq* quadrato-quadrato-quadratus or 8th power, *cc* the cubocubus or 9th power, &c.—Chap. 7, gives a long account of the composition of the cube of a binomial, and the extraction of the cube root, from the theorem $c^3 = (a+b)^3 = a^3 + b^3 + 3ab \cdot a + 3ab \cdot b$, from Tartaglia.—Chap. 8, &c, treats on proportion, arithmetical, geometrical, and harmonical, with the arithmetic of ratios.—Chap. 15, 16, on the single and double rule of Hypothesis, or Position.—Chap. 17, on finding several mean proportionals, by the double rule of Hypothesis, with its application to the celebrated problem of doubling the cube; also to its tripling, and quadrupling, &c.

Book 11. Chap. 1. On the values of the powers, (or what are now called their exponents), being the numbers of their situation in the scale of powers, 1, 2, 3, 4, &c.—Chap. 2, on the addition of the powers, by means of their signs *p* and *m*, that is, plus and minus.—Chap. 3, 4, on the multiplication and division of powers, by adding and subtracting their values or indices.—Chap. 5, 6, addition and subtraction of complex quantities, with mixed signs, *p* and *m*, and various powers.—Chap. 7, 8, multiplication and division of mixed quantities. Here the author states that in these operations, like signs produce *p* (plus), but unlike signs *m* (minus); and he says he has proved these in his Arithmetic, which no one has done before him.—Chap. 9, 10, &c, on finding the sides or roots of simple and compound quantities.

Book 111. *On Equations.* Chap. 1, 2, 3, on simple equations.—Chap. 4, 5, 6, 7, 8, 9, on quadratic equations, by the usual method of completing the square, &c. In the case $x^2 + n = ax$, the author assigns the two roots. In the other two cases, he finds one root only, without noticing the negative roots.—In chap. 10, he speaks of the cubic equations treated of by Cardan and Tartaglia, but without stating the rules for their solution. In chap. 11, 12, 13, some Diophantine problems are treated of.

Book iv, titled *De Quantitate Absoluta et Surda*, contains two chapters. These include various problems or questions, in which several unknown quantities are required to be found, from as many proposed independent relations. In the solution of these questions, the author uses the capitals A, B, C, D, &c., for the unknown quantities to be found, which he employs in the same way as we do now the letters x, y, z, &c., making out with them as many independent equations as are the unknown letters, A, B, C, &c.; by the reduction of which equations, in the usual way, the values of these letters are determined.—But Stifelius, before him, had used A, B, C, &c., for the unknown quantities.

CLAVIUS.

Christopher Clavius wrote his Algebra about the year 1580, though it was not published till 1608, at Orleans. He mostly follows Stifelius and Scheubelinus in his notation and method, &c., having scarcely any variations from them; nor does he treat of cubic equations. He mentions the names given to the art, and the opinions about its origin, in which he inclines to ascribe it to Diophantus, from what Diophantus says in his preface to Dionysius.

STEVINUS.

The Arithmetic of Simon Stevin of Bruges, was published in 1585, and the same with his Algebra in 1605, in the Flemish dialect, and containing a free translation of the first 4 books of Diophantus. They were also printed in a French edition of his works at Leyden in 1634, with some notes and additions of Albert Girard, who it seems died the year before, this edition being published for the benefit of Girard's widow and children. This edition contains all the 6 books of Diophantus.

The Algebra is an ingenious and original work. He denotes the *res*, or unknown quantity, in a way of his own, namely by a small circle O, within which he places the numeral exponent of the power, as ①, ②, ③, ④, &c., which are the 0, 1, 2, 3, &c., power of the quantity O; where ①, or the 0 power, is the beginning of quantity, or arithmetical unit. He also extends this notation to roots or fractional exponents, and even to radical ones.

Thus ②, ③, ④, &c., are the square root, cube root, 4th root, &c.; also ⑤ is the cube root of the square; and ⑥ is the square root of the cube. And so of others.

The first three powers, ①, ②, ③, he also calls *coste* (side), *quare* (square), *cube* (cube); and the first of them, ①, the prime quantity, which he observes is also *metaphorically* called the racine or root, (the mark of which is also ✓), because it represents the root or origin from which all other quantities spring or arise, called the *potences* or powers of it. He condemns the terms *sursolidis*, and *numbers absurd, irrational, irregular, inexplicable, or surd*, and shows that all numbers are denoted the same way, and are all equally proper expressions of some length or magnitude, or some power of the same root. He also rejects all the compound expressions of square-squared, cube-squared, cube-cubed, &c.; and observes that it is best to name them all by their exponents, as the 1st, 2d, 3d, 4th, 5th, 6th, &c., power or quantity in the series. And on his extension of the new notation he justly observes, that what was before obscure, laborious, and tiresome, will by these marks be clear, easy, and pleasant. He also makes the notation of algebraic quantities more general in their coefficients, including in them not only integers, as 3 ①, but also fractions and radicals, as $\frac{2}{3}$ ②, and $\sqrt{2}$ ③,

&c. He has various other peculiarities in his notations; all showing an original and inventive mind. A quantity of several terms, he calls a multinomial, and also binomial, trinomial, &c., according to the number of the terms. He uses the signs + and -, and sometimes : for equality; also × for division of fractions, or to multiply crosswise thus, $\frac{2}{3} \cdot \frac{3}{4} : \frac{1}{2} \cdot \frac{1}{3}$.

He teaches the generation of powers by means of the annexed table of numbers, which are the coefficients of all the terms, except the first and last. And he makes use of the same numbers also for extracting all roots whatever: both which things had first been done by Stifelius. In extracting the roots of non-quadratate or non-cubic numbers, he has the same approximations as at present, viz, either to continue the extraction indefinitely in decimals, by adding periods of ciphers, or by making a fraction of the remainder in this manner, viz, $\sqrt[n]{n} = n + \frac{n - n^2}{2n + 1}$ nearly,

and $\sqrt[3]{n} = n + \frac{n - n^2}{3n^2 + 3n + 1}$ nearly; where n is the nearest exact root of n; which is Peletarius's rule, and which differs from Tartalea's rule, as this wants the 1 in the denominator. And in like manner he goes on to the roots of higher powers.

He then treats of equations, and their inventors, which according to him are thus:

Mahomet, son of Moses, an Arabian, { ① égale à ① invented these - - - - - { ② égale à ①, ②.

And some unknown author, the derivatives of this.

Some unknown author invented these { ③égale à ① ②, { ③égale à ② ③.

But afterwards he mentions Ferreus, Tartalea, Cardan, &c., as being also concerned in the invention of them.

Lewis Ferrari invented - - { ④égale à ② ③ ④ ⑤.

He says also that Diophantus once resolves the case ② égale à ③ ④. In his reduction of equations, which is full and masterly, he always places the highest power on one side alone, equal to all the other terms, set in their order, on the other side, whether they be + or -. And he demonstrates all the rules both arithmetically and geometrically. In cubics, he gives up the irreducible case, as hopeless: but says that Bombelli resolves it by *plus of minus, and minus of minus*:

thus, if $1\circ = 30\circ + 36$, then $1\circ = \sqrt[3]{(18 + of - 26) + \sqrt[3]{(18 - of - 26)}}$, that is, $1\circ = \sqrt[3]{(18 + 26\sqrt{-1}) + \sqrt[3]{(18 - 26\sqrt{-1})}}$. He resolves biquadratics by means of cubics and quadratics. In quadratics, he takes both the two roots, but looks for no more than two in cubics or biquadratics. He gives also a general method of approaching indefinitely near, in decimals, to the root of any equation whatever; but it is very laborious, being little more than trying all numbers, one after another, finding thus the 1st figure, then the 2d, then the 3d, &c., among these ten characters 0, 1, 2, 3, 4, 5, 6, 7, 8, 9. And finally he applies the rules, in the resolution of a great many practical questions.

Though a general air of originality and improvement runs through the whole of Stevinus's work, yet his more remarkable or peculiar inventions, may be reduced to these few following: viz,

1st. He invented not only a new character for the unknown quantity, but greatly improved the notation of

powers, by numeral indices, first given by Stifelius as to integral exponents; which Stevinus extended to fractional and all other sorts of exponents, thereby denoting all kinds of roots the same way as powers, by numeral exponents. A circumstance hitherto thought to be of much later invention.

2d. He improved and extended the use and notation of coefficients, including in them fractions and radicals, and all sorts of numbers in general.

3d. A quantity of several terms, he called generally a multinomial; and he denoted all nomials whatever by particular names expressing the number of their terms, binomial, trinomial, quadrinomial, &c.

4th. A numerical solution of all equations whatever, by one general method.

Besides which, he hints at some unknown author as the first inventor of the rules for cubic equations; by whom may perhaps be intended the author of the Arabic manuscript treatise on cubic equations, given to the library at Leyden by the celebrated Warner.

VIETA.

Most of Vieta's algebraical works were written about or before the year 1600, but some of them were not published till after his death, which happened in the year 1613, in the 63d year of his age. And his whole mathematical works were collected together by Francis Schooten, and elegantly printed in a folio volume in 1646. Of these, the algebraical parts are as follow :

1. Isagoge in Artem Analyticam.
2. Ad Logisticaen Speciosam Notæ Priors.
3. Zeteticorum libri quinque.
4. De Æquationum Recognitione, et Emendatione.
5. De Numerosâ Potestatuum ad Exgesin Resolutione.

Of all these I shall give a particular account, especially in such parts as contain any discoveries, as we here meet with more improvements and inventions on the nature of equations, than in almost any former author. And first of the *Isagoge*, or Introduction to the Analytic Art. In this short introduction Vieta lays down certain *præcognita* in this art; as definitions, axioms, notations, common precepts or operations of addition, subtraction, multiplication, and division, with rules for questions, &c. From which we find, 1st, That the names of his powers are latus, quadratum, cubus, quadrato-quadratum, quadrato-cubus, cubo-cubus, &c; in which he follows the method of Diophantus, and not that derived from the Arabians. 2d, That he calls powers pure or affected, and first here uses the terms coefficient, affirmative, negative, specious logistics or calculations, homogeneum comparationis, or the absolute known term of an equation, homogeneum, affectionis, or the 2d or other term which makes the equation affected, &c. 3d, That he uses the capital letters to denote the known as well as unknown quantities, to render his rules and calculations general; namely the vowels **A**, **E**, **I**, **O**, **U**, **Y** for the unknown quantities, and the consonants, **B**, **C**, **D**, &c, for the known ones. 4th, That he uses the sign + between two terms for addition; — for subtraction, placing the greater before the less; and when it is not known which term is the greater, he places = between them for the difference, as we now use ~; thus **A** = **B** is the same as **A** ~ **B**; that he expresses division by placing the terms like a fraction, as at present; though he was not first in this. But that he uses no characters for multiplication or equality, but writes the words themselves, as well as the names of all the powers, as he uscs

no exponents, which causes much trouble and prolixity in the progress of his work; and the numeral coefficients set after the literal quantities, have a disagreeable effect.

II. *Ad Logisticaen Speciosam Notæ Priors*. These consist of various theorems concerning sums, differences, products, powers, proportionals, &c, with the genesis of powers from binomial and residual roots, and certain properties of rational right-angled triangles.

III. *Zeteticorum libri quinque*. The zetetics or questions, in these 5 books, are chiefly from Diophantus, but resolved more generally by literal arithmetic. And in these questions are also investigated rules for the resolution of quadratic and cubic equations. In these also Vieta first uses a line drawn over compound quantities, as a vinculum.

IV. *De Æquationum Recognitione, et Emendatione*. These two books, which contain Vieta's chief improvements in algebra, were not published till the year 1615, by Alexander Anderson, a learned and ingenious Scotchman, with various corrections and additions. The 1st of these two books consists of 20 chapters. In the first six chapters, rules are drawn from the zetetics for the resolution of quadratic and cubic equations. These rules are by means of certain quantities in continued proportion, but in the solution they come to the same thing as Cardan's rules. In the cubics, Vieta sometimes changes the negative roots into affirmative, as Cardan had done, but he finds only the affirmative roots. And he here refers the irreducible case to angular sections for a solution, a method which had been mentioned by Bombelli.

Chap. 7 treats of the general method of transforming equations, which is done either by changing the root in various ways, namely by substituting another instead of it which is either increased or diminished, or multiplied or divided, by some known number, or raised or depressed in some known proportion; or by retaining the same root, and equally multiplying all the terms. Which kinds of transformation, it is evident, are intended to make the equation become simpler, or more convenient for solution. And all or most of these reductions and transformations were also practised by Cardan.

Chap. 8 shows what purposes are answered by the foregoing transformations; such as taking away some of the terms out of an equation, and particularly the 2d term, which is done by increasing or diminishing the root by the coefficient of the 2d term, divided by the index of the first: by which means also the affected quadratic is reduced to a simple one. And various other effects are produced.

Chap. 9 shows how to deduce compound quadratic equations from pure ones, which is done by increasing or diminishing the root by a given quantity, being one application of the foregoing reductions.

Chap. 10, the reduction of cubic equations affected with the 1st power, to such as are affected with the 2d power; by the same means.

In chap. 11, by the same means also the 2d term is restored to such cubic equations as want it.

In chap. 12, quadratic and cubic equations are raised to higher degrees, by substituting for the root, the square or cube of another root divided by a given quantity.

In chap. 13, affected biquadratic equations are deduced from affected quadratics in this manner, when expressed in the modern notation. If $a^2 + BA = z$, then shall $a^4 + B^3 + 2Bz \cdot a = z^2 + B^2z$.

For since $A^2 + BA = z$, therefore $A^2 = z - BA$, and its square is $A^4 = z^2 - 2BAz + B^2A^2$; but $B^2A^2 = B^2z - B^2A$, therefore $A^4 = z^2 - 2BAz + B^2z - B^2A$, or $A^4 + B^2 + 2Bz \cdot A = z^2 + B^2z$.

And in like manner for the biquadratic affected with its other terms. And in a similar manner also, in chap. 14, affected cubic equations are deduced from the affected quadratics.

In chap. 15 it is shown that the quadratic $BA - A^2 = z$ has two values of the root A , or has ambiguous roots, as he calls them; and also that the cubics, biquadratics, &c., which are raised or deduced from that quadratic, have also double roots.

Having in the foregoing chapters, shown how the coefficients of equations of the 3d and 4th degree are formed from those of the 2d degree, of the same root; and that certain quadratics, and others raised from them, have double roots; then in the 16th chap. Vieta shows what relation those two roots bear to the coefficients of the two lowest terms of an equation consisting of only three terms.

Chap. 17 contains several theorems concerning quantities in continued geometrical progression. Which are preparatory to what follows, concerning the double roots of equations, the nature of which he expounds by means of such properties of proportional quantities.

Chap. 18. *Æquationum aincipitum constitutiva*; treating of the nature of the double roots of equations.

Next follows the 2d of the pieces published by Alexander Anderson, namely,

De Emendatione Æquationum, in 14 chapters.

Chap. 1. Of preparing equations for their resolution in numbers, by taking away the 2d term; by which affected quadratics are reduced to pure ones, and cubic equations affected with the 2d term are reduced to such as are affected with the 3d only. Several examples of both kinds of equations are given. He here too remarks on the method of taking away any other term out of an equation, when the highest power is combined with that other term only; and this Vieta effects by means of the coefficients, or, as he calls them, the unciae of the power of a binomial. All which was also performed by Cardan for the same purpose.

Chap. 2. *De transmutatione Ηγετῶν—Ξατῶν, que remedium est adversus vitium negacionis*. Concerning the transformations by changing the given root a for another root ε , which is equal to the homogeneum comparationis divided by the first root A ; by which means negative terms are changed to affirmative, and radicals are taken out of the equation when they are contained in the homogeneum comparationis.

Chap. 3. *De Anastrophe*, showing the relation between the roots of correlate equations; whence, having given the root of the one equation, that of the other becomes known.

Chap. 4. *De Isomaria, adversus vitium fractionis*. To take away fractions out of an equation. Thus,

$$\text{If } A^3 + \frac{B}{D}A = z. \text{ Put } A = \frac{E}{D}; \text{ then } E^3 + BDE = zD^3.$$

Chap. 5. *De Symmetrica Climacismo, adversus vitium asymmetrie*. To take away radicals or surds out of equations, by squaring, &c., the other side of the equation.

Chap. 6. To reduce biquadratic equations by means of cubics and quadratics, by methods which are small variations from those of Ferrari and Cardan.

Chap. 7. The resolution of cubic equations by rules which are the same with Cardan's.

Chap. 8. *De Canonica æquationum transmutatione, ut coefficientes subgraduale sint qua prescribuntur*. To transmute the equation so that the coefficient of the lower term, or power, may be any given number, he changes the root in the given proportion, thus: Let a be the root of the equation given, E that of the transmuted equation, b the given coefficient, and x the required one; then take $A = \frac{BE}{x}$, which substitute in the given equation, and it is done.—He commonly changes it so, that x may be 1; which he does, that the numeral root of the equation may be the easier found; and this he here performs by trials, by taking the nearest root of the highest power alone: and if that does not turn out to be the root of the whole equation, he concludes that it has no rational root.

Chap. 9. To reduce certain peculiar forms of cubics to quadratics, or to simpler forms, much the same as Cardan had done.

Chap. 10. *Similium reductionum continuatio*. Being some more similar theorems, when the equation is affected with all the powers of the unknown quantity A .

Chap. 11, 12, 13 relate also to certain peculiar forms of equations, in which the root is one of the terms of a certain series of continued proportionals.

Chap. 14, which is the last in this tract, contains in four theorems, the general relation between the roots of an equation and the coefficients of its terms, when all its roots are positive.

And from these last four theorems it appears, that Vieta was acquainted with the composition of these equations, that is, when all their roots are positive, for he never advert to negative roots; and from other parts of the work it appears, that he was not aware that the same properties will obtain in all sorts of roots whatever. But it is not certain in what manner he obtained these theorems, as he has not given any account of the investigations, though that was usually his way on other occasions; but he here contents himself with barely announcing the theorems, and for this strange reason, that he might at length bring his work to a conclusion.

To this piece is added, by Alexander Anderson, an Appendix, containing the construction of cubic equations by the trisection of an angle; and a demonstration of the property referred to by Vieta for this purpose.

De Numerosa Potestatum Purarum Resolutione. Vieta here gives some examples of extracting the roots of pure powers, in the way that had been long before practised, by pointing the number into periods of figures according to the index of the root to be extracted, and then proceeding from one period to another, in the usual way.

De Numerosa Potestatum adfectorum Resolutione. And here, in close imitation of the above method for the roots of pure powers; Vieta extracts those of affected ones; or finding the roots of affected equations, placing always the homogeneum comparationis, or absolute term, on one side, and all the terms affected with the unknown quantity, and their proper signs, on the other side. The method is very laborious, and is but little more than what was before done by Stevinus on this subject, depending not a little on trials. The examples he uses are such as have either one or two roots, and indeed such as are affected commonly with only two powers of the unknown quantity, and which therefore admit only of these two

varieties as to the number of roots, namely according as the higher of the two powers is affirmative or negative, the homogeneum comparationis, on the other side of the equation, being always affirmative; and he remarks this general rule, if the higher power be negative, the equation has two roots, otherwise only one; that is, affirmative roots; for as to negative and imaginary ones, Vieta knew nothing about them, or at least he takes no notice of them. By the foregoing extraction, Vieta finds both the greater and less root of the two that are contained in the equation, and either of them that he pleases; having first, for this purpose, laid down some observations concerning the limits within which the two roots are contained. Also, having found one of the roots, he shows how the other root may be found by means of another equation, which is a degree lower than the given one; though not by depressing the given equation, by dividing it as is now done; but from the nature of proportionals, and the theorems relating to equations, as given in the former tracts, he finds the terms of another equation, different from that last mentioned, from the root &c of which, the 2d root of the original equation may be obtained.

In the course of this work, Vieta makes also some observations on equations that are ambiguous, or have three roots; namely, that the equation $1c - 6q + 11n = 6$, or as we write it $x^3 - 6x^2 + 11x = 6$, is ambiguous, when the 2d term is negative, and the 3d term affirmative, and when $\frac{1}{2}$ of the square of 6, the coefficient of the 2d term, exceeds 11, the coefficient of the 3d term, and has then three roots. Or in general, if $x^3 - ax^2 + bx = c$, and $\frac{1}{2}a^2 > b$, the equation is ambiguous, and has three roots. He shows also, from the relation of the coefficients, how to find whether the roots are in arithmetical progression or not, and how far the middle root differs from the extremes, by means of a cubic equation of this form $x^3 - bx = c$. In all or most of which remarks was preceded by Cardan.—Vieta also remarks that the case $x^3 - 9x^2 + 24x = 20$, has three roots by the same rule, viz, 2, 2, 5, but that two of them are equal. And further, that when $\frac{1}{2}a^2$ is $= b$, then all the three roots are equal, as in the case $x^3 - 6x^2 + 12x = 8$, the three roots of which are 2, 2, 2. But when $\frac{1}{2}a^2$ is less than b , the case is not ambiguous, having but one root. And when $ab = c$, then $a = x$ is one root itself.

Many curious notes are added at the end, with remarks on the method of finding the approximate roots, when they are not rational, which is done in two ways, in imitation of the same thing in the extraction of pure powers, viz, the one by forming a fraction of the remainder after all the figures of the homogeneum comparationis are exhausted; the other by increasing the root of the equation in a 10 fold, or 100 fold, &c, proportion, and then dividing the root which results by 10, or 100, &c: and this is a decimal approximation. And Vieta observes, that the roots will be increased 10 or 100 fold, &c, by adding the corresponding number of ciphers to the coefficient of the 2d term, double that number to the 3d, triple the same number to the 4th, and so on. So if the equation were $1c + 4q + 6n = 8$, then $1c + 40q + 600n = 8000$ will have its root 10 fold, and $1c + 400q + 60000n = 8000000$ will have it 100 fold.

Besides the foregoing algebraical works, Vieta gave various constructions of equations by means of circles and right lines, and angular sections, which may be considered as an algebraical tract, or a method of exhibiting the roots of certain equations having all their roots affir-

mative, and by means of which he resolved the celebrated equation of 45 powers, proposed to all the world by Adrianus Romanus.

Having now delivered a particular analysis of Vieta's algebraical writings, it will be proper, as with other authors, to collect into one view the particulars of his more remarkable peculiarities, inventions, and improvements.

And first it may be observed, that his writings show great originality of genius and invention, and that he made alterations and improvements in most parts of algebra; though in other parts and respects his method is inferior to some of his predecessors; as, for instance, where he neglects to avail himself of the negative roots of Cardan; the numeral exponents of Stifelius, instead of which he uses the names of the powers themselves; or the fractional exponents of Stevinus; or the commodious way of prefixing the coefficient before the quantity or factor; and such like circumstances; the want of which gives his Algebra the appearance of an age much earlier than its own. But his real inventions of things before not known, may be reduced to the following particulars.

1st. Vieta introduced the general use of the letters of the alphabet, to denote indefinite given quantities; which had only been done on some particular occasions before his time. But the general use of letters, for the unknown quantities, was before pretty common with Stifelius and his successors. Vieta uses the vowels A, E, I, O, U, Y for the unknown quantities, and the consonants, B, C, D, &c, for known ones.

2d. He invented, and introduced, many expressions or terms, several of which are in use to this day: such as coefficient, affirmative and negative, pure and affected or affected, unciae, homogeneum adfectionis, homogeneum comparationis, the line or vinculum over compound quantities, thus $\overline{a + b}$. And his method of setting down his equations, is to place the homogeneum comparationis, or absolute known term, on the right-hand side alone, and on the other side all the terms which contain the unknown quantity, with their proper signs.

3d. In most of the rules and reductions for cubic and other equations, he made some improvements, and variations in the modes.

4th. He showed how to change the root of an equation in a given proportion.

5. He derived or raised the cubic and biquadratic, &c, equations, from quadratics; not by composition in Harriot's way, but by squaring and otherwise multiplying certain parts of the quadratic. And as some quadratic equations have two roots, therefore the cubics and others raised from them, have also the same two roots, and no more. And hence he comes to know what relation these two roots bear to the coefficients of the two lowest terms of cubic and other equations, when they have only 3 terms, namely, by comparing them with similar equations so raised from quadratics. And, on the contrary, what the roots are, in terms of such coefficients.

6. He made some observations on the limits of the two roots of certain equations.

7. He stated the general relation between the roots of certain equations and the coefficients of its terms, when the terms are alternately plus and minus, and none of them are wanting, or the roots all positive.

8. He extracted the roots of affected equations, by a method of approximation similar to that for pure powers.

9. He gave the construction of certain equations, and

exhibited their roots by means of angular sections; before adverted to by Bombelli.

OF ALBERT GIRARD.

Albert Girard was an ingenious Dutch or Flemish mathematician, who died about the year 1633. He published an edition of Stevinus's Arithmetic in 1625, augmented with many notes; and the year after his death was published, by his widow, an edition of the whole works of Stevinus, in the same manner, which Girard had left ready for the press. But the work which entitles him to a particular notice in this history, is his "Invention Nouvelle en l'Algèbre, tant pour la solution des équations, que pour reconnoître le nombre des solutions qu'elles reviennent, avec plusieurs choses qui sont nécessaires à la perfection de ceste divine science;" which was printed at Amsterdam 1629, in small quarto, in 63 pages, viz, 49 pages on arithmetic and algebra, and the rest on the measure of the superficies of spherical triangles and polygons, by him then lately discovered.

In this work, Girard first premises a short tract on Arithmetic; in the notation of which he has something peculiar, viz, dividing the numbers into the ranks of millions, billions, trillions, &c.

He next delivers the common rules of algebra, not only in integers and fractions, but radicals also; with the notation of the quantities and signs. In this part he uses sometimes the letters a , b , c , &c, after the manner of Vieta, but more commonly the characters of Stevinus, viz, \oplus , \ominus , \otimes , \div , &c, for the powers of the unknown quantity, with their roots $\sqrt{}$, $\sqrt[3]{}$, $\sqrt[4]{}$, &c, used by Stevinus; and sometimes the more usual marks of the roots, as $\sqrt{}$ or $\sqrt[2]{}$, $\sqrt[3]{}$, &c; prefixing the coefficients, as $6\sqrt{2}$, or $3\sqrt[3]{3}$, or $2\sqrt[4]{2}$. In the signs he follows his predecessors so far as to have + for plus, - or \div for minus, = for general or indefinite difference, $a + b$ for the sum, $a - b$ or $a = b$ for the difference, ab the product, and $\frac{a}{b}$ for the quotient of a and b . He uses the parentheses () for the vinculum or bond of compound quantities, as is now commonly practised; as $a(ab + bc)$, or $\sqrt[3]{(a \text{ cub.} - 3ab^2)}$; and he introduces the new characters ff for greater than, and § for less than; but he uses no character for equality, only the word itself.

Girard gives a new rule for extracting the cube root of binomials, which however is in a good measure tentative, and which he explains thus: To extract the cube root of $72 + \sqrt{5120}$.

$$\text{The squares of the terms } \left\{ \begin{array}{l} 5184 \\ 5120 \end{array} \right.$$

their difference 64, and its cube

root 4. Which shows that the difference between the squares of the terms required is 4; and the rational part 72 being the greater, the greater term of the root will be rational also; and further, that the greater terms of the power and root are commensurable, as also the two less terms. Then having made a table as in the margin, where the square of the rational term always exceeds that of the other, by the number 4 above mentioned, one of these binomials must be the cubic root sought, if the given quantity have such a root; and it must be one of these four forms; for it is known to be carried far enough by observing that the cube root of 72 is less than 5, and the cube root of 5120 less than 21; indeed, this being the case, the last binomial is excluded, as evidently

too great; and the first is excluded because one of its terms is 0; therefore the root must be either $3 + \sqrt{5}$ or $4 + \sqrt{12}$. And to know whether of these two it must be, try which of them has its two terms exact divisors of the corresponding terms of the given quantity; then it is found that 3 and 4 are both divisors of 72, but that only 5, and not 12, is a divisor of 5120; therefore $3 + \sqrt{5}$ is the root sought, which upon trial is found to answer. It is remarkable here, that Girard uses $4 + \sqrt{20}$ instead of $4 + \sqrt{12}$, and $5 + \sqrt{29}$ instead of $5 + \sqrt{20}$, contrary to his own rule.

Girard then gives distinct and plain rules for bringing questions to equations, and for the reduction of those equations to their simplest form, for solution, by the usual modes, and also by the way called by Vieta *Isomeria*, multiplying the terms of the equation by the terms of a geometrical progression, by which means the roots are altered in the proportion of 1 to the ratio of the progression. He then treats of the methods of finding the roots of the several kinds of equations, quadratic, cubic, &c; and adds remarks on the proper number of conditions or equations for limiting questions. The quadratics are resolved by completing the square, and both the positive and negative roots are taken; and he observes that sometimes the equation is impossible, as @ equ. 6 ① - 25, whose roots, he adds, are $3 + \sqrt{-16}$ and $3 - \sqrt{-16}$.

The cubic equations he resolves by Cardan's rule, except the irreducible case, which he first of any resolves by a table of sines; the other cases he also resolves by tables of sines and tangents; and adds geometrical constructions by means of the hyperbola or the section of angles. He next adds a particular mode of resolving all kinds of equations, that have rational roots, on the principle of the roots being divisors of the last or absolute term, as before mentioned by Peletarius; and then gives the method of approximating to other roots that are not rational, much in the same way as Stevinus.

Having found one root of an equation, by any of the former methods, by means of it he depresses the equation one degree lower, then finds another root, and so on till they are all found; for he shows that every algebraic equation, admits of as many solutions or roots, as there are units in the index of the highest power, which roots may be either positive or negative, or imaginary, or, as he calls them, greater than nothing, or less than nothing, or involved; so the roots of the equation 1 @ equ. 7 ① - 6, are 2, 1, and -3; and the roots of the equation 1 @ equ. 4 ① - 3 are, 1, and 1, and $-1 + \sqrt{-2}$, and $-1 - \sqrt{-2}$.

In depressing an equation to lower degrees, he does not use the method of resolution of Harriot, but that which is derived from the general relation of the roots and coefficients of the terms, which he here fully and universally states, viz, that the coefficient of the 2d term is equal to the sum of all the roots; that of the 3d term equal to the sum of all the products of the roots, taken two by two; that of the 4th term, the sum of the products, taken three by three; and so on, to the last or absolute term, which is the continual product of all the roots; a property which was before stated by Vieta, as to the equations that have all their roots positive; and here extended by Girard to all kinds of roots whatever: but how either Vieta or he came by this property, no where appears that I know of. From this general property, among other deductions, Girard shows how to find the sums of the powers of the

roots of an equation; thus, let $a, b, c, d, \&c.$, be the 1st, 2d, 3d, 4th, &c., coefficient, after the first term, or the sums of the products taken one by one, two by two, three by three, &c.; then, in all kinds of equations,

$$\begin{array}{l} A \\ Aq - 2b \\ A cub. - 3Ab + 3c \\ Aqq - 4Aqb + 4Ac + 2Bq - 4b \end{array} \left\{ \begin{array}{l} \text{the roots,} \\ \text{squares,} \\ \text{cubes,} \\ \text{biquadrates.} \end{array} \right. \begin{array}{l} \text{will sum to} \\ \text{the} \end{array}$$

Girard next explains the use of negative roots in geometry, showing that they represent lines only drawn in a direction contrary to those representing the positive roots; and he remarks that this is a thing hitherto unknown. He then terminates the algebra by some questions having two or more unknown quantities. And he subjoins to the whole a tract on the mensuration of the surfaces of spherical triangles and polygons, by him lately discovered.

From the foregoing account it appears that,

1st, He was the first person who understood the general doctrine of the formation of the coefficients of the powers, from the sums of their roots, and their products, &c.

2d, He was the first who understood the use of negative roots in the solution of geometrical problems.

3d, He was the first who spoke of the imaginary roots, and understood that every equation might have as many roots, real and imaginary, and no more, as there are units in the index of the highest power. And he was the first who gave the whimsical name of *quantities less than nothing* to the negative ones.

4th, He was also the first who discovered the rules for summing the powers of the roots of any equation.

OF HARRIOT.

Thomas Harriot, an excellent astronomer, philosopher, and mathematician, was born at Oxford in 1560. After taking the degree of bachelor of arts in 1579, he accompanied the famous Sir Walter Raleigh in an expedition to Virginia, where the first English establishment was made. Harriot here drew the map of the country, and in 1588 gave a relation of the voyage. Being returned to his country, it appears that he gave himself up entirely to the study of the mathematics, and especially to that of algebra. He remained not long unknown to the earl of Northumberland, a great encourager of the sciences, who maintained several learned men, such as Rob. Hues, Walter Warner, and Nathaniel Tarporley. This enlightened nobleman entertained Harriot in his house, with a salary of £300 sterling a-year, a great sum in those times; and in this situation it was that Harriot finished his days, in the year 1621, at 61 years of age. It appears by Kepler's letters, that he held a correspondence with this astronomer, chiefly on the theory of the rainbow. Harriot's manuscripts, lately discovered in the castle of the earl of Egremont, inform us of many of his astronomical observations, and particularly of those of the spots in the sun as early as the beginning of December 1610, while the first of those of Galileo were not made before the preceding month. So that Harriot must then either have made himself a telescope, or procured one from Holland. He made in the same year also, observations on Jupiter's satellites, and on the remarkable comets of the years 1607 and 1618.

His Algebra was left behind him unpublished, as well as those other papers, at his death, which happened in the year 1621, as before mentioned, and but 6 years after the first publication of the principal parts of Vieta's Algebra, by Alexander Anderson; so that it is probable that

Harriot's Algebra was written long before this time, and indeed that he had never seen these pieces.

Harriot's Algebra was published by his friend Walter Warner, in the year 1631: and it would doubtless be highly grateful to the learned in these sciences, if his other curious algebraical and astronomical works were published, from his original papers in the possession of the earl of Egremont, to whom they have descended from Henry Percy, the earl of Northumberland, that noble Maecenas of his day. The book is in folio, and entitled Artis Analyticae Praxis, ad Equations Algebraicas nova expedita, et generali methodo, resolvendas; a work in all parts of it showing marks of great genius and originality, and is the first instance of the modern form of algebra, in which it has ever since appeared. It is prefaced by 18 definitions, which are these: 1st, Logistica Speciosa; 2d, Equation; 3d, Synthesis; 4, Analysis; 5, Composition and Resolution; 6, Forming an Equation; 7, Reduction of an Equation; 8, Verification; 9, Numerosa et Speciosa; 10, Excoigata; 11, Resolution; 12, Roots, 13 and 14, The kinds and generation of equations by multiplication, from binomial roots or factors, called original equations:

$$\begin{array}{l} \text{as } a + b = aa + ba \\ \text{or } a - c = -ca - bc, \quad \begin{array}{l} \text{or } a + b = aaa + lba + lca \\ \text{or } a + c = caa - lba \\ \text{or } a - d = daa - rda - bcd; \end{array} \end{array}$$

where he puts a for the unknown quantity, and the small consonants, $b, c, d, \&c.$, for its literal values or roots. 15, The first form of canonical equations, which are derived from the above originals, by transposing the homogeneous, or absolute term, thus $aa + ba$

$$- ca = + bc, \&c.$$

16, The secondary canonicals, formed from the primary by expelling the 2d term, thus $aa = + bb,$

$$\text{or } aaa - bba$$

$$- bca$$

$$- cca = + bbb$$

$$+ bcc.$$

17, That these are called canonicals, because they are adapted to canons or rules for finding the numeral roots, &c. 18, Reciprocal equations, in which the homogeneous is the product of the coefficients of the other terms, and the first term, or highest power of the root, is equal to the product of the powers in the other terms, as $aaa - caa + bba = + bbb.$

After these definitions, the work is divided into two principal parts; 1st, of various generations, reductions, and preparations of equations for their resolution in the 2d part. The former is divided into 6 sections as follows.

Sect. 1. *Logistica Speciosa*, exemplified in the 4 operations of addition, subtraction, multiplication, and division; as also the reduction of algebraic fractions, and the ordinary reduction of irregular equations to the form proper for the resolution of them, namely, so that all the unknown terms be on one side of the equation, and the known term on the other, the powers in the terms ranged in order, the greatest first, and the first or highest power made positive, and freed from its coefficient; as $aa + ba = cd;$ or $aaa + bba - cda = - cd.$

In this part he explains some unusual characters which he introduces, namely, $=$ for equality, as $a = b,$
 $>$ for majority, as $a > b,$
 $<$ for minority, as $a < b;$
 but the first had been before introduced by Robert Recorde.

Sect. 2. The generation of original equations from binomial factors or roots, and the deducing of canonicals from the originals. He supposes that every equation has as many roots as dimensions in its highest power; then supposing the values of the unknown letter a in any equation to be $b, c, d, f, \&c.$, that is $a = b$, and $a = c$, and $a = d, \&c.$; by transposition, or equal subtraction, these become $a - b = 0$, and $a - c = 0$, and $a - d = 0, \&c.$, or the same letters with contrary signs for negative values or roots; then two of these binomial factors, multiplied together, give a quadratic equation, three of them a cubic, four of them a biquadratic, and so on, with all the terms on one side of the equation, and 0 on the other side, since, every binomial factor being $= 0$, the continual product of all of them must also be = 0.

And these operations are carried through all the cases of the 2d, 3d, and 4th powers, as to the varieties of the signs + and -, and the proportions of the roots as to equal and unequal, with the reciprocals, &c. From which are made evident, at one glance of the eye, all the relations and properties between the roots of equations, and the coefficients of the terms.

Sect. 3. *Æquationum canoniarum secundiarum a primariis reducتو per gradus alicujus parodici sublationem radice suppositiæ invariata manente.* Containing a great many examples of preparing equations, by taking away the 2d, 3d, or any other of the intermediate terms, which is done by making the positive coefficients in that term, equal to the negative ones, by which means the whole term vanishes, or becomes equal to nothing. They are extended as far as equations of the 5th degree; and at the end are collected, and placed in regular order, all the secondary canonicals, so reduced; so that by the uniform law which is visible through them all, the series may be continued to the higher degrees as far as we please.

Sect. 4. *Æquationum canoniarum tam primariarum, quam secundiarum, radicum designatio.* A great many literal equations are here set down, and their roots assigned from the form of the equation, that is, all their positive roots; for their negative roots are not noticed here; and it is every where proved that they cannot have any more positive roots than these, and consequently the rest are negative. That those are roots, he proves by substituting them instead of the unknown letter a in the equation, when they make all the terms on one side come to the same thing as the homogeneum on the other side.

Sect. 5. *In qua aequationum communium per canoniarum æquipollentiam, radicum numerus determinatur.* On the number of the roots of common equations, that is the positive roots. This Harriot determines by comparing them with the like cases found among his canonical forms, which two equations, having the same number of terms with the same signs, and the relations of the coefficients and homogeneum correspondent, he calls equipollents. And whatever was the number of positive roots used in the composition of the canonical, the same, he infers, is the number in the proposed common equation. It is remarkable that, in all the examples here used, the number of positive roots is just equal to the number of the changes in the signs from + to - and from - to +, which is a circumstance, though not here expressly mentioned, that could not escape the observation, or the eye, of any one, much less of so clear and comprehensive a sight as that of Harriot.

In this section are contained many ingenious disquisi-

tions, concerning the limits and magnitudes of quantities, with several curious lemmas laid down to demonstrate the propositions by, which lemmas are themselves demonstrated in a pure mathematical way, from the magnitudes themselves, independent of geometrical figures; such as, 1, If a quantity be divided into any two unequal parts, the square of half the quantity will be greater than the product of the two unequal parts. 2, In three continued proportionals, the sum of the extremes is greater than double the mean. 3, In four continued proportionals, the sum of the extremes is greater than the sum of the two means. 4, In any two quantities, one-fourth the square of the sum of the cubes, is greater than the cube of the product of the two quantities. 5, Of any two quantities q and r , then $\frac{1}{27}(qq + qr + rr)^3 > \frac{1}{4}(qqr + qrr)^2$. 6, If any quantity be divided into three unequal parts, the square of $\frac{1}{3}$ of the whole quantity is greater than $\frac{1}{3}$ of the sum of the three products made of the three unequal parts. 7, Also the cube of the $\frac{1}{3}$ part of the whole, is greater than the solid or continual product of the three unequal parts.

Sect. 6. *Æquationum communium reductio per gradus aliqui parodici exclusionem et radicis suppositiæ mutationem.* Here are a great many examples of reducing and transforming equations of the 2d, 3d, and 4th degrees; chiefly either by multiplying the roots of equations in any proportion, as was done by Vieta, or increasing or diminishing the root by a given quantity, after the manner of Cardan. The former of these reductions is performed by multiplying the terms of the equation by the corresponding terms of a geometrical progression, the first term being 1, and the 2d term the quantity by which the root is to be multiplied. And the other reduction, or transforming to another root, which may be greater or less than the given root by a given quantity, is performed commonly by substituting $e + or - b$ for the given root a , by which the equation is reduced to a simpler form. Other modes of substitution are also used; one of which is this, viz, substituting $\frac{ee \pm bb}{e}$ or $c \pm \frac{bb}{e}$ for the root a in the given equation $aaa \mp 3.bba = 2.ccc$, by which it reduces to this quadratic form $e^6 \mp 2e^3c^3 = b^6$, from which Cardan's forms are immediately deduced; namely, $e = \sqrt[3]{3} c^3 - \sqrt[3]{c^6 \pm b^6}$, and therefore a or $e \pm \frac{bb}{e} = \sqrt[3]{3} c^3 + \sqrt[3]{c^6 \pm b^6 \pm \sqrt[3]{3}} c^3 - \sqrt[3]{c^6 \pm b^6}$; where he denotes the cubic or 3d root thus, $\sqrt[3]{3}$, but without any vinculum over the compound quantities.

In this section, Harriot makes various remarks as they occur; thus, he remarks, and demonstrates, that $ee - 3.bb = -ccc - 2.bbb$ is an impossible equation, or has no affirmative root. He remarks also that the three cases of the equation $aaa - 3.bba = +2.ccc$ are similar to the three conic sections; namely to the hyperbola when $c > b$, to the parabola when $c = b$, or to the ellipsis when $c < b$, and for which reason this case is not generally resoluble in species.

Having thus shown how to simplify equations, and prepare them for solution, Harriot enters next upon the second part of his work, being the

Eregetice Numerosa,

or the numeral resolution of all kinds of equations by a general method, which is exemplified in a great number of equations, both simple and affected, as far as the 5th power inclusive; and they are commonly prepared, by

the foregoing parts, by freeing them from their 2d term, &c. These extractions are explained and performed in a way different from that of Vieta; and the examples are first in perfect or terminate roots, and afterwards for irrational or interminate ones, to which Harriot approximates, by adding always periods of ciphers to the given number or resolvent, as far as necessary in decimals, which are continued and set down as such, but with their proper denominator 10, or 100, or 1000, &c.

He then concludes the work with

Canones Directorii,

which form a collection of the cases or theorems for making the foregoing numeral extractions, ready arranged for use, under the various forms of equations, with the factors necessary to form the several resolvents and substrahends.

And from a review of the whole work, it appears that Harriot's inventions, peculiarities, and improvements in algebra, may be comprised in the following particulars.

1st. He introduced the uniform use of the small letters, $a, b, c, d, \&c.$, viz, the vowels $a, e, \&c.$ for unknown quantities, and the consonants $b, c, d, f, \&c.$ for the known ones; which he joins together like the letters of a word, to represent the multiplication or product of any number of these literal quantities, and prefixing the numeral coefficient as we do at present, except only separated by a point, thus $5.bbc$. For a root, he set the index of the root after the mark $\sqrt{\cdot}$; as $\sqrt[3]{9}$ for the cube root. He also introduced the characters $>$ and $<$, for greater and less; and in the reduction of equations, he arranged the operations in separate steps or lines, setting the explanations in the margin on the left hand, for each line. By which, and other means, he may be considered as the introducer of the modern state of algebra, which quite changed its form under his hands.

2d. He showed the universal generation of all the compound or affected equations, by the continual multiplication of as many simple ones, or binomial roots; thereby plainly exhibiting to the eye the whole circumstances of the nature, mystery and number of the roots of equations; with the composition and relations of the coefficients of the terms; and from which many of the most important properties have since been deduced.

3d. He greatly improved the numeral exegesis, or extraction of the roots of all equations, by clear and explicit rules and methods, drawn from the foregoing generation or composition of affected equations of all degrees.

OF OUGHTRED'S CLAVIS.

Oughtred was contemporary with Harriot, but lived a long time after him, as he died only in 1660, at 87 years of age. His Clavis was first published in 1631, the same year in which Harriot's Algebra was published by his friend Warner. In this work, Oughtred chiefly follows Vieta, in the notation by the capitals $A, B, C, D, \&c.$, in the designation of products, powers, and roots, though with some few variations. His work may be comprehended under the following particulars.

1. *Notation.* This extends to both algebra and arithmetic, vulgar and decimal. The algebra chiefly after the manner of Vieta, as abovesaid. And he separates the decimals from the integers thus $21\frac{1}{2}6$, which is the first time I have observed such a separation, and the decimals set down without their denominator.

2. The common rules or operations of arithmetic and

algebra. In algebraic multiplication, he either joins the letters together like a word, or connects them by the mark \times , which is the first introduction of this character of multiplication: thus $A \times A$ or AA or ag . But omitting the vinculum over compound factors, used by Vieta. He introduces here many neat and useful contractions in multiplication and division of decimals: as that common one of inverting the multiplier, to have fewer decimals, and abridge the work; that of omitting always one figure at a time, of the divisor, for the same purpose; dividing by the component factors of a number instead of the number itself; as 4 and 6 for 24; and many other neat contractions. He states his proportions thus $7.9 :: 28.36$, and denotes continued proportion thus $\cdots :: \cdots$; which is the first time I have observed these characters.

3. Invents and describes various symbolical marks or abbreviations, which are not now used.

4. *The genesis and analysis of powers.* Denotes powers like Vieta, and also roots, thus $\sqrt{ab}, \sqrt{c20}, \sqrt{gg24}, \&c.$; and much in his manner too performs the numeral extraction of roots. He here gives a table of the powers of the binomial $A + E$ as far as the 10th power, with all their terms and coefficients, or unciae as he calls them, after Vieta.

5. *Equations.* He here gives express and particular directions for the several kinds of reductions, according as the form of the equation may require. He uses the letter u after $\sqrt{\cdot}$, for universal, instead of the vinculum of Vieta. And he observes that the signs of all the terms of the powers of $A + E$ are positive, but those of $A - E$ are alternately positive and negative.

6. Next follow many properties of triangles and other geometrical figures; and the first instance of applying algebra to geometry, so as to investigate new geometrical properties; also, after the algebraical resolution of each problem, he commonly deduces and gives a geometrical construction adapted to it. He gives also a good tract on angular sections.

7. The work concludes with the numeral solution of affected equations, in which he follows the manner of Vieta, though he is more explicit.

OF DESCARTES.

Descartes's Geometry was first published in 1637, being six years after the publication of Harriot's Algebra. That work was rather an application of algebra to geometry, than the science either of algebra or geometry itself, purely and properly so called. And yet he made improvements in both. We must observe, however, that all the properties of equations, &c., which he sets down, are not to be considered as even meant by himself for new inventions or discoveries; but as statements and enumerations of properties, before known and taught by other authors, which he is about to make some use or application of, and for which reason it is that he mentions those properties.

Descartes's Geometry consists of three books. The first of these is, *De Problematibus, quae construi possunt, adhibendo tautum rectas lineas et circulos.* He here accommodates or performs arithmetical operations by geometry, supposing some line to represent unity, and then, by means of proportionals, showing how to multiply, divide, and extract roots, by lines. He next describes the notation he uses, but not because it is a new one, for it is the same as had been used by former authors, viz, $a + b$ for the addition of a and b , also $a - b$ for their subtraction.

tion, ab multiplication, $\frac{a}{b}$ division, aa or a^2 the square of a , a^3 its cube, &c: also $\sqrt{a^2 + b^2}$ for the square root of $a^2 + b^2$, and $\sqrt{c.a^2 - b^2 + abb}$ for the cube root, &c, with a bar over the quantities. He then observes, after Stifelius, that there must be as many equations as there are unknown lines or quantities; and that they must be reduced all to one final equation, by exterminating all the unknown letters except one; when the final equation will appear like these,

$$z \gg b, \text{ or}$$

$$z^2 \gg -ax + b^2, \text{ or}$$

$$z^2 \gg +az^2 + b^2z - c^3, \text{ or}$$

$$z^4 \gg +az^3 + b^2z^2 - c^2z + d^4, \text{ &c.}$$

Where he uses \gg for $=$ or equality, setting the highest term or power alone on one side of the equation, and all the other terms on the other side, with their proper signs.

Descartes next defines plane problems, namely, such as can be resolved by right lines and circles, described on a plane superficies; and then the final equation rises only to the 2d power of the unknown letter. He then constructs such equations, viz, quadratics, by the circle, thus finding geometrically the root or roots, that is, the positive ones. But when the lines, by which the roots are determined, neither cut nor touch, he observes that the equation has then no possible root, or that the problem is impossible. He then concludes this book with the algebraical solution of the celebrated problem, before treated of by the ancients, namely, to find a point, or the locus of all the points, from which a line being drawn, to meet any number of given lines in given angles, the product of the segments of some of them shall have a given ratio to that of the rest.

Book 2. *De Natura Linearum Curvarum.* This is a good algebraical treatise on curve lines in general, and the first of the kind that has been produced by the moderns. Here the nature of the curve is expressed by an equation containing two unknown or variable lines, and others that are known or constant, as $y^2 \gg cy - \frac{cxy}{b} + ay - ac$. But, not relating to pure algebra, the particulars will be most properly placed under the article of curve lines, and other terms relating to them. Only one discovery, among many ingenious applications of algebra to geometry, may here be particularly noticed, as it may be considered as the first step towards the arithmetic of infinites; and that is the method of tangents, here given, or, which comes to the same thing, of drawing a line perpendicular to a curve at any point; which is an ingenious application of the general form of an equation, generated in Harriot's way, that has two equal roots, to the equation of the curve. Of which a particular account will be given at the article TANGENTS.

Book 3. *De Constructione Problematum Solidorum, et Solida excedentium.* Descartes begins this book with remarks on the nature and roots of equations, observing, that they have as many roots as dimensions, which he shows, after Harriot, by multiplying a certain number of simple binomial equations together, as $x - 2 \gg 0$, and $x - 3 \gg 0$, and $x - 4 \gg 0$, producing $x^3 - 9xx + 26x - 24 \gg 0$. He here remarks that equations may sometimes have their roots false, or what we call negative, which he opposes to those that are positive, or as he calls them true, as Cardan had done before. As a natural deduction from the generation or composition of equations,

by multiplication, he infers their resolution, or depression, or decomposition, namely, dividing them by the binomial factors which were multiplied to produce the equation: and he observes, that, by this operation it is known that this divisor is one of the binomial roots, and that there can be no more roots than dimensions, or than those which form with the unknown letter x , binomials that will exactly divide the equation, as Harriot had shown before.

Descartes adverts to several other properties, mostly known before, which he has occasion to make use of in the progress of his work; such as, that equations may have as many true roots as the terms have changes of the signs + and -, and as many false ones as successions of the same signs; which number and nature of the roots had before been partly shown by Cardan and Vieta, from the relation of the coefficients, and their signs, and the same thing appears more fully by Harriot's 5th section. And hence Descartes infers the method of changing the true roots to false, and the false to true, namely, by changing the signs of the even terms only, as Cardan had taught before. Descartes then adverts to other reductions and transmutations which had been taught by Cardan, Vieta, and Harriot, such as, To increase or diminish the roots by any quantity; To take away the 2d term; To alter the roots in any proportion, and thence to free the equation from fractions and radicals.

Descartes next remarks that the roots of equations, whether true or false, may be either real or imaginary; as in the equation $x^3 - 6xx + 13x - 10 \gg 0$, which has only one real root, namely 2. The imaginary roots were first noticed by Albert Girard, as before mentioned. He then treats of the depression of a cubic equation to a quadratic, or plane problem, that it may be constructed by the circle, by dividing it by some one of the binomial factors, which, in Harriot's way, compose the equation. Peletarius having shown that the simple root is one of the divisors of the known term of the equation, and Harriot that that term is the continual product of all the roots, Descartes therefore tries all the simple divisors of that term, till he finds one of them which, connected with the unknown letter x , by + or -, will exactly divide the equation. And the process is the same for higher powers than the cube. But when a divisor cannot be thus found, for depressing a biquadratic equation to a cubic, he gives another rule, which is a new one, for dissolving it into two quadratics, by means of a cubic equation, in this manner:

Let the given biqu. be $+x^4 + pxx . qx . r \gg 0$;

Which suppose } equal to the $+xx - yx + \frac{1}{2}yy \cdot \frac{q}{2p} \cdot \frac{q}{2y} \gg 0$;

product of } $+xx + yx + \frac{1}{2}yy \cdot \frac{q}{2p} \cdot \frac{q}{2y} \gg 0$;

where the sign of $\frac{1}{2}p$ in the two quadratics must be the same as the sign of p in the given equation, and in the 1st quadratic the sign of $\frac{q}{2y}$ must be the same as the sign of q , but in the 2d quadratic the contrary. Then if there be found the root yy of this cubic equation $y^6 - 2py^4 + \frac{pp}{4r}yy - qy \gg 0$, where the sign $2p$ is the same as of p in the given biquadratic, but the sign of $4r$ contrary to that of r in the same; then the value of y , hence deduced, being substituted for it in the two quadratic equations, and their two pairs of roots taken, they will be the four roots of the proposed biquadratic. And thus also, he

hints, may equations of the 6th power be reduced to those of the 5th, and those of the 8th power to those of the 7th, and so on. Descartes does not give the investigation of this rule; but it has evidently been done, by assuming indeterminate quantities, after the manner of Ferrari and Cardan, as coefficients of the terms of the two quadratic equations, and after multiplying the two together, determining their values by comparing the resulting terms with those of the proposed biquadratic equation.

After these reductions, which are only mentioned for the sake of the geometrical constructions which follow, by simplifying and depressing the equations as much as they will admit, Descartes then gives the construction of solid and other higher problems, or of cubic and higher equations, by means of parabolas and circles; where he observes, that the false roots are denoted by the ordinates to the parabola lying on the contrary side of the axis to the true roots, as before mentioned by Girard. Finally, these constructions are illustrated by various problems concerning the trisecting of an angle, and the finding of two or four mean proportionals; which concludes this ingenious work.

From the foregoing analysis may easily be collected the real inventions and improvements made in algebra by Descartes. His work, as has been observed before, is not algebra itself, but the application of algebra to geometry, and the algebraical doctrine of curve lines, expressing and explaining their nature by algebraical equations; and, on the contrary, constructing and explaining equations by means of the curve lines. What respects the geometrical parts of this tract we shall have occasion to advert to elsewhere; and therefore shall here only enumerate the circumstances which belong more peculiarly to the science of algebra, which I shall distinguish into the two heads, of improvements, and inventions. And

1st. Of his improvements.—That he might fit equations the better for their application in the construction of problems, Descartes mentions, as it were by-the-by, many things concerning the nature and reduction of equations, without troubling himself about the first inventors of them, stating them in his own terms and manner, which is commonly more clear and explicit, and often with improvements of his own. And under this head we find that he chiefly followed Cardan, Vietea, and Harriot, but especially the last, and explains some of their rules and discoveries more distinctly, and varies but a little in the notation, putting the first letters of the alphabet for the known, and the latter letters for the unknown quantities; also x^3 for aaa , &c.; and ∞ for $=$. But Herigone used the numeral exponents in the same manner some years before, as well as several older authors. Descartes explained or improved most parts of the reductions of equations, in their various transmutations, the number and nature of their roots, true and false, real and what he denominates imaginary, called involved by Girard; and the depression of equations to lower degrees.

2d. As to his inventions and discoveries in algebra, they may be comprised in these particulars: namely, the application of algebra to the geometry of curve lines, the constructing equations of the higher orders, and a rule for resolving biquadratic equations by means of a cubic and two quadratics.

Having now traced the science of algebra from its origin and rude state, down to its modern and more polished form, in which it has ever since continued, with very

little variation; having analysed all or most of the principal authors, in a chronological order, and deduced the inventions and improvements made by each of them; from this time the authors both become too numerous, and their improvements too inconsiderable, to merit a detail in the same minute and circumstantial way: and besides, these will be better explained in a particular manner under the word or article to which each of them severally belongs. It may therefore now suffice to enumerate, or announce only in a cursory way, the chief improvements and authors on algebra down to the present time.

After the publication of the Geometry of Descartes, a great many other ingenious men followed the same course, applying themselves to algebra and the new geometry, to the mutual improvement of them both; which was done chiefly by reasoning on the nature and forms of equations, as generated and composed by Harriot. Before proceeding upon these, however, it is but proper to take notice here of Fermat, a learned and ingenious mathematician, who was contemporary and a competitor of Descartes, for his brightest discoveries, which he was in possession of before the geometry of Descartes appeared. Namely, the application of algebra to curve lines, which he expressed by an algebraical equation, and by them constructed equations of the 3d and 4th orders; also a method of tangents, and a method de maximis et minimis, which approach very near to the method of fluxions or increments, which they strikingly resemble, both in the manner of treating the problems, and in the algebraic notation and process. The particulars of which, see under the proper heads. Besides these, Fermat was deeply learned in the Diophantine problems, and the best edition of Diophantus's Arithmetic, is that which contains the notes of Fermat on that ingenious work.

But to return to the successors of Descartes. His geometry having been published in Holland, several learned and ingenious mathematicians, of that country, presently applied themselves to cultivate and improve it; as Schooten, Hudde, Van-Heuraet, De Witte, Slusius, Huygens, &c.; besides M. de Beaune, and perhaps some others in France.

Francis Schooten, professor of mathematics in the university of Leyden, was one of the first cultivators of the new geometry. He translated Descartes's geometry out of French into Latin, and published it in 1649, with his commentary on it, as also Brief Notes of M. de Beaune; both of them containing many ingenious and useful things. And in 1659 he gave a new edition of the same, in two volumes, with the addition of several other ingenious pieces: as, two posthumous tracts of de Beaune, the one on the nature and constitution, the other on the limits of equations, showing how to assign the limits between which are contained the greatest and least roots of equations, extended and completed by Erasmus Bartholine: two letters of M. Hudde on the reduction of equations, and on the maxima and minima of quantities, containing many ingenious rules; among which are some concerning the drawing of tangents, and on the equal roots of equations, which he determines by multiplying the terms of the equation by the terms of any arithmetical progression, 0 being one of the terms, the equation is commonly depressed one degree lower; also a tract of Van Heuract on the rectification of curve lines; the elements of curves by De Witte; Bartholine's principles of universal mathe-

matics, or introduction to Descartes's geometry, which had before been published by itself in 1651; and to the end of the work is added a posthumous piece of Schooten's (for he died while the 2d vol. was printing) entitled *Tractatus de concinnandis demonstrationibus geometricis ex calculo algebraico*. Schooten also published, in 1657, *Exercitationes Mathematicæ*, in which are contained many curious algebraical and analytical pieces, among others of geometrical nature.

An elaborate commentary on Descartes's geometry, was also published by F. Rabuel, a Jesuit; and James Bernoulli, enriched with notes, an edition of the same, printed at Basil in 169—.

The celebrated Huygens also, among his great discoveries, very much cultivated the algebraical analysis: and he is often cited by Schooten, who relates divers inventions of his, while he was his pupil.

Sliusius, a canon of Liege, published in 1659, *Mesolabum, seu duæ mediae propor. per circulum et ellips. vel hyperb. infinitis modis exhibitæ*; by which, any solid problem may be constructed by infinite different ways. And in 1668, he gave a second edition of the same, with the addition of the analysis, and a miscellaneous collection of curious and important problems, relating to spirals, centres of gravity, maxima and minima, points of inflexion, and some Diophantine problems; all showing him deeply skilled in algebra and geometry.

There have been a great number of other writers and improvers of algebra, of which it may suffice slightly to mention the chief part, as in the following catalogue.

In 1619 several pieces of Van Collen, or Ceulen, were translated out of Dutch into Latin, and published at Leyden by W. Snell; among which are contained a particular treatise on surds, and his proportion of the circumference of a circle to its diameter.

In 1621 Bachet published, in Greek and Latin, an edition of Diophantus, with many notes. And another edition of the same was published in 1670, with additions by Fermat.

In 1624 Bachet's *Problemes Plaisans et Delectables*, being curious problems in mathematical recreations.

In 1634 Herigone published, at Paris, the first course of mathematics, in 5 vols. 8vo; in the 2d of which is contained a good treatise on algebra; in which he uses the notation by small letters, introduced by the algebra of Harriot, which was published three years before, though the rest of it does not resemble that work, and one would suspect that Herigone had not seen it. The whole of this piece bears evident marks of originality and ingenuity. Besides + for plus, he uses ~ for minus, and 2|2 for equality, with several other useful abbreviations and marks of his own. In the notation of powers, he does not repeat the letters like Harriot, but subjoins the numeral exponents to the letter, as Descartes did two years afterwards. And Herigone uses the same numeral exponents for roots, as $\sqrt{3}$ for the cube root.

In 1635 Cavalieri published his Indivisibles; which proved a new era in analytics, and gave rise to other new modes of computation in analytics.

About 1640, et seqq. Roberval made several notable improvements in analytics, which are published in the early volumes of the *Memoirs of the Academy of Sciences*; as, 1, A tract on the composition of motion, and a method of tangents. 2, *De recognitione æquationum*. 3, *De geo-*

metria planarum et cubicarum æquationum resolutione. 4, A treatise on indivisibles, &c.

In 1643 De Billy published *Nova Geometriæ Clavis Algebra*. And in 1670 Diophantus Redivivus. He was an author particularly well skilled in Diophantine problems.

In 1644 Renaldine published, in 4to, *Opus Algebraicum*, both ancient and modern, with mathematical resolution and composition. And in 1665, in folio, the same, greatly enlarged, or rather a new work, which is very heavy and tedious. In this work Renaldine uses the parentheses $(a^2 + b^2)$ as a vinculum, instead of the line over, as $\overline{a^2 + b^2}$.

In 1655 was published Wallis's *Arithmetica Infinitorum*, being a new method of reasoning on quantities, or a great improvement on the indivisibles of Cavalieri, and which in a great measure led the way to infinite series, the binomial theorem, and the method of fluxions. Wallis here treats ingeniously of quadratures and many other problems, and gives the first expression for the quadrature of the circle by an infinite series. Another series is here added for the same purpose, by the Lord Brouncker, the first pres. of the R. S.

In 1659 was published, at Zurich in Switzerland, *Algebra Rhonii Germanice*; which was, in 1668, translated into English by Mr. Thomas Brancker, with additions and alterations by Dr. John Pell.

In 1661 was published in Dutch, a neat piece of Algebra by Mr. Kinckhuysen; which Sir Isaac Newton, while he was professor of mathematics at Cambridge, made use of and improved, and he meant to republish it, with the addition of his method of fluxions and infinite series; but was prevented by the accidental burning of some of his papers.

In 1665 or 1666 Sir Isaac Newton made several of his brightest discoveries, though they were not published till afterwards: such as the binomial theorem; the method of fluxions and infinite series; the quadrature, rectification, &c, of curves; to find the roots of all kinds of equations, both numeral and literal, in infinite converging series; the reversion of series, &c. Of each of which a particular account may be seen in their proper articles.

In 1666 M. Frencile gave several curious tracts concerning combinations, magic squares, triangular numbers, &c; which were printed in the early volumes of the *Memoirs of the Academy of Sciences*.

In 1668 Thomas Brancker published a translation of Rhonius's Algebra, with many additions by Dr. John Pell, who used a peculiar method of registering the steps in any algebraical process, by means of marks and abbreviations in a small column drawn down the margin, by which each line, or step, is clearly explained, as was before done by Harriot in words at length. This book contains a valuable table of prime numbers.

In 1668 Mercator published his *Logarithmotecnia*, or method of constructing logarithms; in which he gives the quadrature of the hyperbola, by means of an infinite series of algebraical terms, found by dividing a simple algebraic quantity by a compound one, and for the first time that this operation was given to the public, though Newton had before that expanded all sorts of compound algebraical quantities into infinite series.

In the same year was published James Gregory's *Exercitationes Geometricæ*, containing, among other

things), a demonstration of Mercator's quadrature of the hyperbola, by the same series.

And in the same year was published, in the Philosophical Transactions, Lord Brouncker's quadrature of the hyperbola, by another infinite series of simple rational terms, which he had been in possession of since the year 1657, when it was announced to the public by Dr. Wallis. Lord Brouncker's series for the quadrature of the circle had been published by Wallis in his Arithmetic of Infinites, as before mentioned.

In 1669 Dr. Isaac Barrow published his Optical and Geometrical Lectures, abounding with profound researches on the dimensions and properties of curve lines; but particularly to be noticed here for his method of tangents, by a mode of calculation similar to that of fluxions, or increments, from which these differ but little, except in the notation. Of these lectures, the 13th merits the most special notice, being entirely employed on equations, and delivered in a very curious way. He there treats of the nature and number of their roots, and the limits of their magnitudes, from the description of lines accommodated to each, viz., treating the subject as a branch of the doctrine of maxima and minima, which in the opinion of some persons is the right way of considering them, and as far preferable to the so much boasted invention of the generation of equations from each other, explained by Harriot and Descartes.

In 1673 was published, in 2 vols. folio, Elements of Algebra, by John Kersey; a very ample and complete work, in which Diophantus's problems are fully explained.

In 1675 were published Nouveaux Elemens des Mathematiques, par J. Prestet, prêtre: a prolix and tedious work, which he presumptuously dedicated to God Almighty.

About 1677 Leibnitz discovered his Methodus Differentialis, or else made a variation in Newton's Fluxions, or an extension of Barrow's method, for it is not certain which. He gave the first instance of it in the Leipsic Acts for the year 1684. He also improved infinite series, and gave a simple one for the quadrature of the circle, in the same acts for 1682. But this series had before been found by Mr. James Gregory, viz., in 1671.

In 1682 Ismael Bulliald published, in folio, his Opus Novum ad Arithmeticanam Infinitorum, being a large amplification of Wallis's Arithmetic of Infinites.

In 1683 Tschirnhausen gave a memoir, in the Leipsic Acts, concerning the extraction of the roots of all equations in a general way; in which he promised too much, as the method did not succeed.

In 1684 came out, in English and Latin, 4to, Thomas Baker's Geometrical Key, or Gate of Equations Unlocked; being an improvement of Descartes's construction of all equations under the 5th degree, by means of a circle and only one and the same parabola for all equations, using any diameter instead of the axis of the parabola.

In 1685 was published, in folio, Wallis's Treatise of Algebra, both Historical and Practical, with the addition of several other pieces; exhibiting the origin, progress, and advancement of that science, from time to time. It cannot be denied that, in this work, Wallis has shown too much partiality to the Algebra of Harriot. Yet, on the other hand, it is as true, that M. de Gua, in his account of it, in the Memoirs of the Academy of Sciences for 1741,

has run at least as far into the like extreme on the contrary side, with respect to the discoveries of Viete; and both these I believe from the same cause, namely, the want of examining the works of all former writers on algebra, and specifying their several discoveries; as has been done in the course of this article.

In 1687 Dr. Halley gave, in the Philos. Trans. the construction of cubic and biquadratic equations, by a parabola and circle; with improvements on what had been done by Descartes, Baker, &c. Also, in the same Transactions, a memoir on the number of the roots of equations, with their limits and signs.

In 1690 was published, in 4to, by M. Rolle, *Traité d'Algèbre*; in 1699, *Une Méthode pour la Resolution des Problèmes indéterminés*; and in 1704, *Mémoires sur l'inverse des tangents*; and other pieces.

In 1690 Joseph Raphson published *Analysis Æquationum Universalis*; being a general method of approximating to the roots of equations in numbers. And in 1715 he published the History of Fluxions, both in English and Latin.

In 1690 was also published, in 4 vols 4to, Dechale's *Cursus seu mundus mathematicus*; in which is a piece of algebra, of a very old-fashioned sort, considering the time when it was written.

About 1692, and at different times afterwards, De Lagny published many pieces on the resolution of equations in numbers, with many theorems and rules for that purpose.

In 1693 was published, in a neat little volume, *Synopsis Algebraica*, opus posthumum Johannis Alexandri.

In 1694 Dr. Halley gave, in the Philos. Trans. an ingenious tract on the numeral extraction of all roots, without any previous reduction. And this tract is also added to some editions of Newton's Universal Arithmetic.

In 1695 Mr. John Ward, of Chester, published, in 8vo, A Compendium of Algebra, containing plain, easy, and concise rules, with examples in an easy and clear way. And in 1706 he published the first edition of his Young Mathematician's Guide, or a plain and easy introduction to the mathematics: a book which is still in great request, especially with beginners, and which has been ever since the ordinary introduction of the greatest part of the mathematicians of this country.

In 1696 the Marquis de l'Hôpital published his *Analyse des infinités petits*; and gave several papers to the Leipsic Acts and the Memoirs of the Academy of Sciences. He left behind him also an ingenious treatise, which was published in 1707, entitled *Traité analytique des Sections Coniques, et de la construction des lieux géométriques*.

In 1697, and several other years, M. Ab. Démovre gave various papers in the Philos. Trans. containing improvements in algebra; viz., in 1697, a method of raising an infinite multinomial to any power, or extracting any root of the same. In 1698, The extraction of the root of an infinite equation. In 1707, Analytical solution of certain equations of the 3d, 5th, 7th, &c, degree. In 1722, Of algebraic fractions and recurring series. In 1738, The reduction of radicals into more simple forms. Also in 1730, he published *Miscellanea analytica de seriebus et quadraturis*, containing great improvements in series, &c.

In 1698 Mr. Richard Sault published, in 4to, A New Treatise of Algebra, apply'd to numeral questions and

geometry. With a converging series for all manner of Adfected Equations. The series here alluded to, is Mr. Raphson's method of approximation, which had been lately published.

In 1699 Hyac. Christopher published at Naples, in 4to, De constructione aequationum.

In 1702 was published Ozanam's Algebra; which is chiefly remarkable for the Diophantine analysis. He had published his mathematical dictionary in 1691, and in 1693 his course of mathematics, in 5 vols. 8vo, containing also a piece on algebra.

In 1704, Dr. John Harris published his Lexicon Technicum, the first dictionary of arts and sciences: a very plain and useful book, especially in the mathematical articles. And in 1705, a neat little piece on algebra and fluxions.

In 1705 M. Guisnēe published, in 4to, his Application de l'Algebre a la geometrie: a useful book.

In 1706 Mr. William Jones published his Synopsis Palmariorum Matheseos, or a new introduction to the mathematics: a very useful compendium in the mathematical sciences. And in 1711 he published, in 4to, a collection of sir Isaac Newton's papers, entitled Analysis per quantitatum series, fluxiones, ac differentias: cum enumeratione linearum tertii ordinis.

In 1707 was published, by Mr. Whiston, the first edition of sir Isaac Newton's Arithmetica Universalis: sive de compositione et resolutione arithmeticæ liber: and many editions have been published since. This work, it seems, was the text-book used by our great author in his lectures, while he was professor of mathematics in the university of Cambridge. And though it was never intended for publication, it contains many and great improvements in analytics; particularly in the nature and transmutation of equations; the limits of the roots of equations; the number of impossible roots; the invention of divisors, both surd and rational; the resolution of problems, arithmetical and geometrical; the linear construction of equations; approximating to the roots of all equations, &c. To the later editions of the book is commonly subjoined Dr. Halley's method of finding the roots of equations. As the principal parts of this work are not adapted to the circumstance of beginners, there have been published commentaries upon it by several persons, as s'Gravesande, Castillion, Wilder, &c.

In 1708 M. Reynaud published his Analyse Demonstrée, in 2 vols, 4to. And in 1714, La Scieenc du Calcul, &c.

In 1709 was published an English translation of Alexander's Algebra. With an ingenious appendix by Humphy Ditton.

In 1715 Dr. Brooke Taylor published his Methodus Incrementorum: an ingenious and learned work. And in the Philos. Trans. for 1718, An improvement of the method of approximating to the roots of equations in numbers.

In 1717 M. Nicole gave, in the memoirs of the academy of sciences, a tract on the calculation of finite differences. And in several following years, he gave various other tracts on the same subject, and on the resolution of equations of the 3d degree, and particularly on the irreducible case in cubic equations: those tracts are grounded on a production of M. Leibnitz in the year 1677.

Also in 1717 was published a Treatise on Algebra by Philip Ronayne.

Also in 1717 Mr. James Sterling published Lineæ

tertiū Ordinis; an ingenious work, containing good improvements in analytics. And in 1730, Methodus Differentialis: sive tractatus de summatione et interpolatione serierum infinitarum: with great improvements on infinite series.

In 1726 and 1729 Maclaurin gave, in the Philos. Trans. tracts on the imaginary roots of equations. And afterwards was published, from his posthumous papers, his Treatise on Algebra, with its application to curve lines.

In 1727 came out s'Gravesande's Algebra, with a specimen of a commentary on Newton's universal arithmetic.

In 1728 Mr. Campbell gave, in the Philos. Trans. an ingenious paper on the number of impossible roots of equations.

In 1732 was published Wofsius's Algebra, in his course of mathematics, in 5 vols, 4to.

In 1735 Mr. John Kirby published his arithmetic and algebra. And in 1748 his doctrine of ultimatores.

In 1740 were published Mr. Thomas Simpson's Essays; in 1743 his Dissertations, and in 1757 his Tracts; in all which are contained several improvements in series and other parts of algebra. As also in his Algebra, first printed in 1745, and in his Select Exercises, in 1752.

Also in 1740 was published professor Saunderson's Éléments of Algebra, in 2 vols, 4to; being a very useful work for beginners.

In 1741 M. de la Caille published Leçons de mathématiques; ou elemens d'algebre et de géometrie.

Also in 1741, in the Memoirs of the academy of sciences, were given two articles by M. de Guia, on the number of positive, negative, and imaginary roots of equations. With an historical account of the improvements in algebra; in which he severely censures Wallis for his partiality: a circumstance in which he himself is not less faulty.

In 1746 M. Clairaut published his Éléments d'algebre, in which are contained several improvements, especially on the irreducible case in cubic equations; chiefly after the manner of Leibnitz and Nicole. He has also several good papers on different parts of analytics, in the Memoirs of the academy of sciences.

In 1747 M. Fontaine gave, in the Memoirs of the academy of sciences, a paper on the resolution of equations. Besides some analytical papers in the memoirs of other years.

In 1761 M. Castillon published, in 2 vols, 4to, Newton's universal arithmetic, with a large commentary.

In 1763 Mr. Emerson published his Increments. In 1764 his Algebra, &c.

In 1764 Mr. Landen published his Residual Analysis. In 1765 his Mathematical Lucubrations. And in 1780 his Mathematical Memoirs. All containing good improvements in infinite series, &c.

In 1770 was published, in the German language, Elements of Algebra by M. Euler, which have been since translated into French and English. And in 1774 a French translation of the same. The memoirs of Berlin and Petersburg academies also abound with various improvements in series and other branches of analysis, by this celebrated mathematician.

In 1775 was published at Bologna, in 2 vols, 4to, Compendio d'Analisi di Girolamo Saladin.

In 1797 was published, by Signor Cossali, in the Italian language, in 2 vols, 4to, a very elaborate history of the origin of the first introduction of algebra into Italy, and

of its progress and more early improvements among his countrymen. In this work, the author clearly shows, what however was well known long before, that the science was imported into Italy from the Arabians; but he seems erroneously to ascribe the very invention of algebra to these latter people, from his ignorance of the discoveries lately made of the writings on this science among the Hindus.

LE GENDRE.

M. Le Gendre published in 1798, at Paris, in 1 vol 4to, his *Essai sur la Théorie des Nombres*, in which all the most interesting properties of numbers are recorded, and faithfully attributed to their respective authors, which is I believe the first book of any importance that was dedicated to this particular subject. The work is divided into four parts, each containing several theorems besides an Introduction at considerable length; and at the end of the book are added several tables relating to the particular forms of divisors which belong exclusively to certain algebraical formulæ, the use and application of which are explained in the body of the work.

The Introduction treats of the particular forms under which prime numbers are contained, and the number of the latter is proved to be infinite. It is also demonstrated that no algebraical formula can express prime numbers only. Lastly, the number of prime numbers b , contained between unity and any given number a , is shown to be very nearly expressed by $b = \frac{a}{2 \log a}$.

Part 1. Contains an explanation of Continued Fractions, and their application to various cases in the indeterminate analysis; among others, a general solution is given in integer numbers to every possible indeterminate equation of the second degree, and a method of judging of the possibility, or impossibility of such equations; this solution, however, is due to La Grange.

The second part commences with the demonstration of several general properties of numbers, most of which are mentioned under that article in this Dictionary. The rest of this part is employed in discovering the forms of divisors which belong exclusively to certain algebraical formulæ, and the application of them for finding prime numbers, with an explanation of the law of reciprocity between the latter.

Part 3. Here numbers are considered as decomposed into three squares, and many properties relating to them are demonstrated. Every number is shown to be the sum of one, two, or three triangular numbers, which is the first demonstration that was given to this part of the celebrated theorem of Fermat.

The fourth part contains the demonstration of some other properties, in which the possibility and impossibility of various formulæ are demonstrated with regard to their being particular powers, thus $x^2 \pm y^2 = z^2$ is impossible, as also $x^4 \pm y^4 = z^4$, and generally $x^n \pm y^n = z^n$ is impossible, when n is greater than 2, but this last has never yet been demonstrated.

In the course of this work some new symbols are occasionally introduced, which however our limits will not permit us to explain.

Several other works have been published by the same author, but as they do not properly fall under this article, they are omitted.

GAUSS.

Soon after the above Essays appeared, M. Gauss pub-

lished a similar work in Latin, afterwards translated into French in 1 vol, 4to, under the title of *Recherches Arithmétiques*. The subject of which is much the same as the former, these two able mathematicians having undertaken the same task at nearly the same time, without knowing each other's intentions; but here the subject is carried to a greater length than in the former. M. Gauss has by an extension of his analysis been able to express the side of a polygon of 17 sides inscribed in a circle by means of a quadratic equation, which was before thought to be impossible; and the same method may be applied to other polygons when the number of their sides is a prime number of a particular form. There are likewise some hints given for forming a table of logarithms, or numbers which may be employed in algebra to great advantage, as common logarithms are in arithmetical computations. In this work many new symbols are introduced, such as \equiv for congruity, that is $a \equiv b$ (to modulus c), when $a \pm b$ is divisible by c , and many others, which cannot be properly understood without an attentive perusal of the work itself.

We are informed by M. Gauss that he had another work in hand, which will carry this interesting subject much farther.

ARBOGAST.

M. Arbogast, professor of mathematics at Strasburgh, published in 1800, in 1 vol, 4to, a work entitled *Du Calcul des Derivations*, which is appropriated entirely to the doctrine of series; where their transformation, summation, interpolation, and reversion, as also various other particulars relating to this intricate branch of analysis, are treated of in a manner, as new and ingenious, as it is profound and learned. By the method here introduced many difficulties are surmounted relating to the higher branches of astronomy, which the *Calcul Differential* was inadequate to encounter with success. It seems, however, that some hints of this method was first given by Dr. Waring in his *Meditations Analytique*, and which, perhaps, furnished Arbogast with the germ of his idea. In this work many new characters are introduced, not to represent quantities, but the operations performed upon them. Thus, let $r(a+x)$ be any function of the binomial $a+x$, we can expand this function in a series proceeding according to the powers of x , in this form, $r(a+x) = a + bx + \frac{c}{1,2} x^2 + \frac{d}{1,2,3} x^3 &c.$ Now, we know that $a = ra$, that b is derived from a , or from ra ; c from b , d from c &c., by the same law; therefore, if we conceive the manner in which we derive b from a , in the same manner we may derive c from b , d from c , &c. Thus representing by r , the operation that must be performed on ra in order to obtain b , we shall have $b = r^2 a$, $c = r^3 ra$, $d = r^4 ra^2$ &c.; so that the above series may be expressed thus, $r(a+x) = ra + \frac{r^2 a}{1} x + \frac{r^3 ra}{1,2} x^2 + \frac{r^4 ra^2}{1,2,3} x^3 &c.$

It is however impossible to give any thing like an adequate idea of the method, or notation, employed in this profound work, in the narrow limits to which we are under the necessity of confining our observations, which have already exceeded the bounds we had at first prescribed to this article.

Besides the foregoing, there have been many other authors who have given treatises on algebra, or who have

made improvements on series and other parts of algebra; as Schonerus, Coignet, Salignat, Laloubere, Hemischius, Degraave, Mescher, Henischius, Roberval, the Bernoullis, Malbranche, Agnesi, Wells, Dodson, Manfredi, Begnault, Bezout, Bossut, Rowning, Maseres, Waring, Lorgna, de la Grange, de la Place, Bertrand, Kuhnius, Hales, and many other authors. Dr. Waring and the Rev. Mr. Vincé, of Cambridge, have both given many improvements and discoveries in series, and in other branches of analysis. Those of Mr. Vincé are chiefly contained in the latter volumes of the Philos. Trans.; where also are several of Dr. Waring's: but the bulk of this gentleman's improvements are contained in his separate publications, particularly the *Meditationes Algebraicæ* published in 1770; the *Proprietates Algebraicarum Curvarum*, in 1772; and the *Meditationes Analyticæ*, in 1776.

For a more enlarged history of algebra, see my Tracts, vol. 2, tract 33.

ALGEBRAICAL, something relating to algebra. Thus we say algebraical solutions, curves, characters or symbols, &c.

ALGEBRAICAL Curve, is a curve in which the general relation between the abscissæ and ordinates can be expressed by a common algebraical equation. These are also called *geometrical lines or curves*, in contradistinction to *mechanical or transcendental ones*.

ALGEBRAIST, a person skilled in algebra.

ALGENEB, or **ALGENIB**, a fixed star of the second magnitude, on the right side of Perseus.

ALGOL, or *Medusa's Head*, a fixed star of the third magnitude, in the constellation Perseus.

ALGORAB, a fixed star of the third magnitude, in the right wing of the constellation Corvus.

ALGORITHM, is similar to logistics, signifying the art of computing in any particular way, or about some particular subject; or the common rules of computing in any art. As the algorithm of numbers, of algebra, of integers, of fractions, of surds, &c; meaning the common rules for performing the operations of arithmetic, or algebra, or fractions, &c.

ALHAZEN, **ALLACEN**, or **ABDILAZUM**, was a learned Arabian, who lived in Spain about the year 1100, according to his editor Risner, and Weidler. He wrote upon astrology; and his work on optics was printed in Latin, at Basil, in 1572, under the title of *Optica Thesaurus*, by Risner. Alhazen was the first who showed the importance of refractions in astronomy, so little known to the ancients. He is also the first author who has treated on the twilight, upon which he wrote a work, in which he likewise speaks of the height of the clouds.

ALIDADE, an Arabic name for the label, index, or ruler, which is moveable about the centre of an astrolabe, quadrant, &c., and carrying the sights or telescope, and by which are shown the degrees cut off the limb or arch of the instrument.

ALIQUANT part, is that part which will not exactly measure or divide the whole, without leaving some remainder. Or the *aliquant* part is such, as being taken or repeated any number of times, does not make up the whole exactly, but is either greater or less than it. Thus 4 is an aliquant part of 10; for 4 twice taken makes 8, which is less than 10; and three times taken makes 12, which is greater than 10.

ALIQUOT part, is such a part of a number as will exactly divide it without a remainder. Or the aliquot

part is such, as being taken or repeated a certain number of times, exactly makes up, or is equal to the whole. So 1 is an aliquot part of 6, or of any other whole number; 2 is also an aliquot part of 6, being contained just 3 times in 6; and 3 is also an aliquot part of 6, being contained just 2 times; so that all the aliquot parts of 6 are 1, 2, 3.

All the aliquot parts of any number may be thus found: Divide the given number by its least divisor; then divide the quotient also by its least divisor; and so on, always dividing the last quotient by its least divisor, till the quotient 1 is obtained; and all the divisors, thus taken, are the prime aliquot parts of the given number. Then multiply continually together these prime divisors, viz, every two of them, every three of them, every four of them, &c; and the products will be the other or compound aliquot parts of the given number. So, if the aliquot parts of 60 be required; first divide it by 2, and the quotient is 30: then 30 divided by 2 also gives 15, and 15 divided by 3 gives 5, and 5 divided by 5 gives 1: so that all the prime divisors or aliquot parts are 1, 2, 3, 5. Then the compound ones, by multiplying every two, are 4, 6, 10, 15; and every three 10, 20, 30. So that all the aliquot parts of the given number 60, are 1, 2, 3, 4, 5, 6, 10, 12, 15, 20, 30.—In like manner it will be found that all the aliquot parts of 360, are 1, 2, 3, 4, 5, 6, 8, 9, 10, 12, 15, 18, 20, 24, 30, 36, 40, 45, 60, 72, 180.

ALLEN (THOMAS), a celebrated mathematician of the 16th century. He was born at Uttoxeter in Staffordshire, in 1542; was admitted a scholar of Trinity college, Oxford, in 1561; where he took his degree of master of arts in 1567. In 1570 he quitted his college and fellowship, and retired to Gloucester hall, where he studied very closely, and became celebrated for his knowledge in antiquity, philosophy, and mathematics. He received an invitation from Henry earl of Northumberland, the great friend and patron of mathematicians, and he spent some time at the earl's house; where he became acquainted with those able mathematicians Thomas Harriot, John Dee, Walter Warner, and Nathaniel Torporley. Robert earl of Leicester, too, had a great esteem for Allen, and would have conferred a bishopric upon him; but his love for solitude and retirement made him decline the offer. His great skill in the mathematics gave occasion to the ignorant and vulgar to look upon him as a magician or conjurer. Allen was very curious and indefatigable in collecting scattered manuscripts relating to history, antiquity, astronomy, philosophy, and mathematics: which collections have been quoted by several learned authors, and mentioned as in the *Bibliotheca Alleniana*. He published in Latin the second and third books of Ptolemy, Concerning the judgement of the Stars, or, as it is usually called, of the quadripartite construction, with an exposition. He wrote also notes on many of Lilly's books, and some on John Bale's work, *De scriptoribus Maj. Britanniae*. He died at Gloucester hall in 1632, at 90 years of age.

Mr. Burton, the author of his funeral oration, calls him the very soul and sun of all the mathematicians of his age. And Selden mentions him as a person of the most extensive learning and consummate judgment, the brightest ornament of the university of Oxford. Camden also says he was skilled in most of the best arts and sciences. A. Wood has also transcribed part of his character from a manuscript in the library of Trinity college, in these words: "He studied polite literature with great application; he was strictly tenacious of academic discipline;

always highly esteemed both by foreigners and those of the university, and by all of the highest stations in the church of England, and the university of Oxford. He was a sagacious observer, an agreeable companion, &c." See Wood, vol. i, p. 492.

ALLIGATION, one of the rules in arithmetic, by which are resolved questions which relate to the compounding or mixing together of divers simples or ingredients, being so called from *alligare*, to tie or connect together, probably from certain *vincula*, or crooked ligatures, commonly used to connect or bind the numbers together:

It is probable that this rule came to us from the Moorish or Arabic writers, as we find it, with all the other rules of arithmetic, in Lucas de Burgo, and other early authors in Europe.

Alligation is of two kinds, *medial* and *alternate*.

ALLIGATION MEDIAL is the method of finding the rate or quality of the composition, from having given the rates and quantities of the simples or ingredients.

The rule of operation is this: multiply each quantity by its rate, and add all the products together; then divide the sum of the products by the sum of the quantities, or whole compound, and the quotient will be the rate sought.

For example; Suppose it were required to mix together 6 gallons of wine, at 5s. a gallon; 8 gallons, at 6s. the gallon; and 4 gallons, at 8s. the gallon; and to find the worth or value, per gallon, of the whole mixture.

Gall.	s.	products.
Here	6	\times 5 = 30
	8	\times 6 = 48
	4	\times 8 = 32
whole comp.	18	110 sum of prod.
Then	18	($10\frac{2}{9}$ or $6\frac{1}{9}$ s.) is the rate sought.
	108	
	2	

ALLIGATION ALTERNATE is the method of finding the quantities of ingredients or simples, necessary to form a compound of a given rate.

The rule of operation is this: 1st, Place the given rates of the simples in a column, under each other. 2d, Connect or link with a continued line, each rate which is less than the proposed compound rate, with one or any number of those that are greater; and every greater rate with one or any number of the less. 3d, Write the difference between the given compound rate and that of each simple opposite the rates with which they are linked. 4th, Then if only one difference stand opposite any rate, it will be the quantity belonging to that rate; but when there are several, their sum will be the quantity.

For example, Suppose it were required to mix together gold of various degrees of fineness, viz, of 19, of 21, and of 23 carats fine, so that the mixture shall be of 20 carats fine. Here,

Rates	Diffs.	Sum of Diffs.
{ 21	--- 1	{ 1 of 21 carats fine,
Comp. rate 20 { 19	--- 1 + 3	{ 4 of 19 carats fine,
{ 23	--- 1	{ 1 of 23 carats fine.

That is, there must be an equal quantity of 21 and 23 carats fine, and 4 times as much of 19 carat fine.

Various limitations, both of the compound and the ingredients, may be conceived; and in such cases, the differences are to be altered proportionally.

Questions of this sort are however commonly best and easiest resolved by common algebra, of which they form

a species of indeterminate problems, as they admit of many, or an indefinite number of answers.

There is recorded a remarkable instance of a discovery made by Archimedes, both by alligation and specific gravity at the same time, namely, concerning the crown of Hiero, king of Syracuse. The king had ordered a crown to be made of pure gold; but when brought to him, a suspicion arose that it was mixed with alloy of either silver or copper, and the king recommended it to Archimedes to discover the cheat, without defacing the crown. Archimedes, after long thinking on the matter, without lighting on the means of doing it, being one day in the bath, and observing how his body raised the water higher, conceived the idea that different metals of the same weight would occupy different spaces, and so raise or expel different quantities of water. Upon which he procured two other masses, each of the same weight with the crown, the one of pure gold, and the other of alloy; then immersing them all three, separately, in water, and observing the space each occupied, by the quantity it raised the water, he thence computed the quantities of gold and alloy contained in the crown.

ALLIOTH, a star in the tail of the great bear. The word in Arabic denotes a horse; and they gave this name to each of the three stars, in the tail of the great bear, as they are placed like three horses, thus arranged for the purpose of drawing the wagon commonly called Charles's wain, represented by the four stars on the body of the same constellation.

ALMACANTAR, or ALMICANTAR, from the Arabic *almakanharat*, are circles parallel to the horizon, and conceived to pass through every degree of the meridian; serving to show the height of the sun, moon, or stars, &c; and are the same as the parallels of altitude.

ALMACANTAR'S STAFF, was an instrument formerly used at sea for observing the sun's amplitude at rising or setting, and thence to determine the variation of the compass, &c.

ALMAGEST, the name of a celebrated book composed by Ptolemy; being a collection of a great number of the observations and problems of the ancients, relating to geometry and astronomy, but especially the latter. Being the first work of this kind which has come down to us, and containing a catalogue of the fixed stars, with their places, besides numerous records and observations of eclipses, the motions of the planets, &c, this work will ever be held dear and valuable to the cultivators of astronomy.

In the original Greek it is called *ouragis meistoria*, the great composition or collection. And to the word *meistoria*, *megistei*, the Arabians joined the particle *al*, and thence called it *Almaghesi*, or, as we call it, from them, the Almagest.

Ptolemy was born about the year of Christ 69, and died in 147: he wrote this work, consisting of 13 books, at Alexandria in Egypt, where the Arabians found it on the capture of that kingdom. It was by them translated out of Greek, into Arabic, by order of the caliph Almanon, about the year 827; and first into Latin about 1230, by favour of the emperor Frederic II. The Greek text however was not known in Europe till about the beginning of the 15th century, when it was brought from Constantinople, then taken by the Turks, by George, a monk of Trabzon, who translated it into Latin, which translation has several times been published.

Riccioli, an Italian jesuit, also published, in 1651, a body of Astronomy, which, in imitation of Ptolemy, he called *Almagestum Novum*, the New Almagest; being a large collection of ancient and modern observations and discoveries, in the science of astronomy.

ALMAMON, caliph of Bagdat, a philosopher and astronomer, in the beginning of the 9th century, having ascended the throne in the year 814. He was son of Harun Al-Rashid, and grandson of Almansor. His name is otherwise written *Mamon*, *Almaon*, *Almanan*, *Alamoun*, or *Al-Maimon*. Having been educated with great care, and possessing a love for the liberal sciences, he applied himself to cultivate and encourage them in his own country. For this purpose he requested the Greek emperors to supply him with such books on philosophy as they had among them; and he collected skilful interpreters to translate them into the Arabic language. He also encouraged his subjects to study them; frequenting the meetings of the learned, assisting at their exercises and deliberations. He caused Ptolemy's Almagest to be translated in 827, by Isaac Ben-honain, and Thabet Ben-korah, according to Herbelot, but according to others by Sergius, and Alhazen, the son of Joseph. In his reign, and doubtless by his encouragement, an astronomer of Bagdat, named Habash, composed three sets of astronomical tables.

Almamon himself made many astronomical observations, and determined the obliquity of the ecliptic to be then $23^{\circ} 35'$ (or $23^{\circ} 33'$ in some manuscripts), but Vossius says $23^{\circ} 31'$ or $23^{\circ} 34'$. He also caused skilful observers to procure proper instruments to be made, and to exercise themselves in astronomical observations; which they did accordingly at Shemasi in the province of Bagdat, and upon Mount Casius near Damas.

Under the auspices of Mamon also a degree of the meridian was measured on the plains of Sinjar or Sindgiar (or according to some Fingar), on the borders of the Red Sea; by which the degree was found to contain $56\frac{2}{3}$ miles, of 4000 coudees each, the coudee being a foot and a half: but it is not known what foot is here meant, whether the Roman, the Alexandrian, or some other. Riccioli makes this measure of the degree amount to 81 ancient Roman miles, which value answers to 62046 French toises; a quantity more than the true value of the degree by almost one-third.

Finally, Mamon revived the sciences in the East to such a degree, that many learned men were found, not only in his own time, but after him, in a country where the study of the sciences had been long forgotten. This learned king died near Tarsus in Cilicia, by having eaten too freely of some dates, on his return from a military expedition, in the year 833.

ALMANAC, a calendar or table, in which are set down and marked the days and feasts of the year, the common ecclesiastical notes, the course and phases of the moon, &c, for each month: and answers to the fasti of the ancient Romans.

The etymology of the word is much controverted among grammarians.—Some derive it from the Arabic, *viz*, from the particle *al*, and *manah*, to count. While Scaliger, and others, derive it from the same *al*, and the Greek *paroxos*, the course of the months. But Golius controverts these opinions, and ascribes the word to another origin, though he still makes it of Arabic extract, which it more evidently is. He says that, in the East, it is the custom for the people, at the beginning of the year, to

Vol. I.

make presents to their princes; and that, among the rest, the astrologers present them with their almanacs, or ephemerides, for the year ensuing; whence these came to be called *almanha*, that is, new-year's gifts. But this derivation seems rather strained and improbable; for, by the same rule, the gifts or productions of other artists, or classes of men, might also be called almanacs. There are other guesses at the etymology; and Verstegan writes the word *almanac*, and makes it of German original. Our ancestors, he observes, used to carve the courses of the moon, for the whole year, upon a square piece of wood, which they called *al-monaugh*, which is as much as to say, in old English or Saxon, *all-moon-head*.

An instrument of this kind, it seems, of a very ancient date, is to be seen in St. John's college at Cambridge; and that in the midland counties there are still several remains of them. An engraved figure of one of them, with a particular description, may be seen in Brady's *Clavis Calendaria*, vol. 1, 1812.

Almanacs are of various kinds and composition, some books, others sheets, &c, some annual, others perpetual. The essential part is the calendar of months, weeks, and days; the motions, changes, and phases of the moon; with the rising and setting of the sun and moon. To these are commonly added various matters, astronomical, astrological, chronological, meteorological, and even political, rural, medical, &c; as also eclipses, solar ingresses, aspects, and configurations of the heavenly bodies, lunations, heliocentric and geocentric motions of the planets, prognostications of the weather, predictions of other events, the tides, twilight, equation of time, &c.

Till about the 4th century, almanacs bore the marks of heathenism only; from thence to the 7th century, they were a mixture of heathenism and Christianity; and ever since they have been altogether Christian: but at all times astrological and other predictions have been considered as an essential part, and are so to this day with several of them, notwithstanding that most people affect to disbelieve in such predictions.

Nautical ALMANAC, and *Astronomical Ephemeris*, is a kind of national almanac, chiefly for nautical purposes, which was begun in the year 1767 under the direction of the Board of Longitude, on the recommendation of the late worthy Astronomer Royal, Dr. Maskelyne, who had the immediate conducting of it. It is still published by anticipation for several years before-hand, for the convenience of ships going out upon long voyages, for which purpose it is highly useful, and was found eminently so in the course of the late voyages round the world for making discoveries. Besides most things essential to general use, that are to be found in other almanacs, it contains many new and important particulars; more especially, the distances of the moon from the sun and fixed stars, which are computed for the meridian of the Royal Observatory of Greenwich, and set down to every three hours of time, expressly designed for computing the longitude at sea, by comparing these with the like distances observed there.

For an explanation of the Hindu almanacs, see *Philos. Trans.* Abridg. vol. 17, p. 250, &c.

ALPHONSINE Tables, are astronomical tables compiled by order of Alphonso, king of Castile, in the compiling of which, it is thought that prince himself assisted. See *Astronomical Tables*.

ALPHONSIUS the 10th, king of Leon and Castile, who has been surnamed The Wise, on account of his attachment

to literature, and is now more celebrated for having been an astronomer than a king. He was born in 1203; succeeded his father Ferdinand the 3d, in 1252; and died in 1284, at the age of 81.

The affairs of the reign of Alphonsus were very extraordinary, and unfortunate for him. But we shall here only consider him in that part of his character, on account of which he has a place in this work, namely, as an astronomer and man of letters. He understood astronomy, philosophy, and history; and composed books upon the motions of the heavens, and on the history of Spain, which are highly commended. "What can be more surprising," says Mariana, "than that a prince, educated in a camp, and handling arms from his childhood, should have such a knowledge of the stars, of philosophy, and the transactions of the world, as men of leisure can scarcely acquire in their retirements? There are extant some books of Alphonsus on the motions of the stars, and the history of Spain, written with great skill and incredible care." In his astronomical pursuits he discovered that the tables of Ptolemy were full of errors; and thence he conceived, the first of any, the resolution of correcting them: For this purpose, about the year 1240, and during the life of his father, he assembled at Toledo the most skilful astronomers of his time, Christians, Moors, or Jews, when a plan was formed for constructing new tables. This task was accomplished about 1252, the first year of his reign; the tables being drawn up chiefly by the skill and pains of Rabbi Isaac Hasan, a learned Jew, and the work called the *Alphonsine Tables*, in honour of the prince, who was at vast expenses concerning them. He fixed the epoch of the tables to the 30th of May 1252, being the day of his accession to the throne. They were printed for the first time in 1483, at Venice, by Radolti, who excelled in printing at that time; which edition is extremely rare; there are others of 1492, 1521, 1545, &c. (Weidler, p. 280.)

We must not omit a memorable saying of Alphonsus, which has been recorded for its boldness and pretended impiety; namely, "that if he had been of God's privy council when he made the world, he could have advised him better." Mariana however says only in general, that Alphonsus was so bold as to blame the works of Providence, and the construction of our bodies; and he says that this story concerning him rested only on a vulgar tradition. The jesuit's words are curious: "Emánuel, the uncle of Sanchez (the son of Alphonsus), in his own name, and in the name of other nobles, deprived Alphonsus of his kingdom by a public sentence: which that prince merited, for daring severely and boldly to censure the works of Divine Providence, and the construction of the human body, as tradition says he did. Heaven most justly punished the folly of his tongue." Though the silence of such an historian as Mariana, in regard to Ptolemy's system, ought to be of some weight, yet we cannot think it improbable, that if Alphonsus did pass so bold a censure on any part of the universe, it was on the celestial sphere, and meant to glance upon the contrivers and supporters of that system. For, besides that he studied nothing more, it is certain that at that time astronomers explained the motions of the heavens by intricate and confused hypotheses, which did no honour to God, nor otherwise answered the idea of an able operator. So that, from considering the multitude of spheres composing the system of Ptolemy, and those numerous eccentric cycles and epi-

cycles with which it is embarrassed, if we suppose Alphonsus to have said, "That if God had asked his advice when he made the world, he would have given him better council," the boldness and impiety of the censure will be greatly diminished, if not entirely removed, as probably meant for a satirical sneer at the intricate devices and contrivances of mortals.

ALSTED (JOHN-HENRY), a German protestant divine, and one of the most indefatigable writers of the 17th century. He was some time professor of philosophy and divinity at Herborn, in the county of Nassau: from thence he went into Transylvania, to be professor at Alba Julia; where he continued till his death, which happened in 1638, at 50 years of age. He applied himself chiefly to compose methods, and to reduce the several branches of arts and sciences into systems. His *Encyclopædia* has been much esteemed, even by Roman catholics: it was printed at Lyons, and sold very well throughout all France. Vossius mentions the *Encyclopædia* in general, but speaks of his treatise of Arithmetic more particularly, and allows the author to have been a man of great reading and universal erudition. His *Thesaurus Chronologicus* is by some esteemed one of his best works, and has gone through several editions, though others speak of it with contempt. In his *Triumphus Biblicus*, Alsted endeavours to prove, that the materials and principles of all the arts and sciences may be found in the Scriptures; but he gained very few to his opinion. John Himmelius wrote a piece against his *Theologia Polemica*, which was one of Alsted's best performances. It seems he was a millenarian, having published, in 1672, a treatise *De Mille Annis*, in which he asserts that the faithful shall reign with Jesus Christ upon earth a thousand years; after which will be the general resurrection, and the last judgment; and he pretended that this reign would commence in the year 1694.

ALTERNATE angles, in Geometry, are the internal angles, α and β , or a and b , made by a line cutting two parallels, and lying on opposite sides of the cutting line. It is the property of these angles to be always equal to each other, namely the angle $\alpha =$ the angle β , and the angle $a =$ the angle b . And the exterior alternate angles are also equal.

ALTERNATE Ratio or Proportion, is the ratio of the one antecedent to the other, or of one consequent to the other, in any proportion, in which the quantities are of the same kind.

So if $\alpha : b :: c : d$,

then alternately, or by alternation, $a : c :: b : d$.

ALTERNATION, or Permutation, of quantities or things, is the varying or changing the order or position of them.

As suppose two things a and b ; these may be placed either thus, ab or ba , that is two ways, or 1×2 . If there be three things, a , b , c : then the 3d thing c , may be placed three different ways with respect to each of the two positions ab and ba of the other two things; it may stand either before them, or between them, or after them both, that is, it may stand either 1st, 2d, or 3d; and therefore, with three things there will be three times as many changes as with two, that is $1 \times 2 \times 3$ or 6 changes with three things. Again, if there be four things a , b , c , d ; then the fourth thing d may be placed in four different ways with respect to each of the six positions of the other three; for it may be set either 1st or 2d or 3d or 4th in

the order of each position; consequently, from four things there will be four times as many alternations as there are from three things; and therefore $1 \times 2 \times 3 \times 4 = 24$ is the number of changes with four things. And so on, always multiplying the last found number of alternations by the next number of things; or to find the number of changes for any number of things, as n , multiply the series of natural numbers 1, 2, 3, 4, 5, &c, to n , continually together, and the last product will be the number of alternations sought; as, $1 \times 2 \times 3 \times 4 \times 5 \cdots n$ is the number of changes in n things.

So if, for example, it were required to find how many changes may be rung on 12 bells; it would be $1 \times 2 \times 3 \times 4 \times 5 \times 6 \times 7 \times 8 \times 9 \times 10 \times 11 \times 12 = 479001600$, the number of changes. Now supposing there might be rung 10 changes in one minute, that is 10×12 or 120 strokes in a minute, or 2 strokes in each second of time; then, according to this rate, it would take upwards of 91 years, without ever ceasing day or night, to ring over all these changes on the 12 bells only. Also, if but two more bells were added, making 14 bells; then, at the same rate of ringing, it would require about 16375 years to ring all the changes on the 14 bells but once over. And if the number of bells were 24, it would require more than 11700000000000000 years to ring all the different changes upon them!

ALTIMETRY, ALTIMETRIA, the art of taking or measuring altitudes or heights, whether accessible or inaccessible. Or Altimetria is that part of practical geometry which relates to the theory and practice of measuring both heights and depths, either in perpendicular or oblique lines.

ALTING (JAMES), was born at Heidelberg in 1618. He travelled into England in 1640, where he was ordained by the learned Dr. Pridgeaux, bishop of Worcester. He afterwards succeeded Gomarus in the professorship of Groningen. He died in 1697; and recommended the edition of his works to Menso Altius (author of *Notitia German. Infer. Antiquæ*); but they were published in 5 vols folio, with his life, by Bekker of Amsterdam. They contain various analytical, exegetical, practical, problematical, and philosophical tracts, which show his great industry and knowledge.

ALTITUDE, in Geometry, is the height of an object, or its elevation above that plane to which its base is referred; so that the altitude of the same object is different in different places; thus, two persons taking the height of a mountain, being on contrary sides of it, will each consider its base as on a level with the place where he stands, and therefore in many cases they will give different results.

ALTITUDE of a figure, is the distance of its vertex from the base, or the length of a perpendicular let fall from its vertex to the base. The altitudes of figures are necessary to be known in computing their areas or solidities.

ALTITUDE, or Height of any point of a terrestrial object, is the perpendicular let fall from that point to the plane of the horizon.

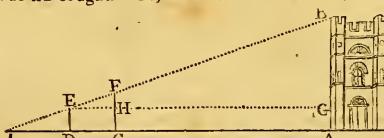

To measure the ALTITUDE of bodies or objects. If this cannot be done by stretching a line from top to bottom, which is the direct and most accurate way, then some indirect way is used, by measuring some other line or distance which may serve as a basis, in conjunction with

angles, or proportional lines, either to compute, or geometrically determine, the altitude of the object sought.

There are various ways of measuring altitudes, or depths, by means of different instruments, and by shadows or reflected images, on optical principles. There are also various ways of computing the altitude in numbers, from the measurements taken as above, either by geometrical construction, or trigonometrical calculation, or by simple numerical computation from the property of parallel lines, &c.

The instruments mostly used in measuring altitudes, are the quadrant, theodolite, geometrical square, line of shadows, &c; the descriptions of each of which may be seen under their respective names.

To measure an altitude geometrically, when we can have access to the base of the object. Suppose the height of the accessible tower AB be required. First, by means of two rods, or staves, of different lengths. Plant the longer staff perpendicularly at C ; then move the shorter backwards, till by trials you find such a place, D , that the eye placed at the top of it at E , may see the top of the other, F , and that of the object B in a straight line: next measure the distances DA or EG and DC or EH , also HF the difference between the heights of the rods: then, by similar triangles, as $EH : EG :: HF : GB$; the 4th proportional GB ; to which add AG or DE , and the sum will be the whole altitude AB sought. Or, as $EH : EA :: FH : BA$.

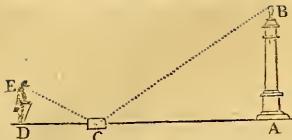

Or, with one rod CF only. Plant it at such a place c , that the eye at the ground, or near it, at A , may see the tops F and B , in a right line: then, having measured $1A$, CF , the 4th proportion to these will be the altitude AB sought.

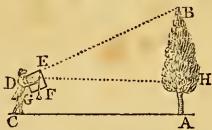

Or thus, by means of shadows. Plant a rod ab perpendicularly at a , and measure its shadow ac , as also the shadow ac of the object AB , at the same instant; then the 4th proportional to ac , ab , AC will be the altitude AB sought. For the angles at b and c being equal, the triangles are similar.

Or thus, by means of optical reflection. Place a vessel of water, or a mirror or other reflecting surface, horizontal at c ; and go to such a distance, d , that the eye E may see the image of the top of the object in the mirror at c : then, by similar figures, $CD : DE :: CA : AB$ the altitude sought. This depends on a property in optics, namely, that the angle of incidence is equal to the angle of reflection, that is, the angle BCA is equal to the angle EDC ; and the angles at A and D being right angles, the two triangles are similar: hence the above proportion. See OPTICS.

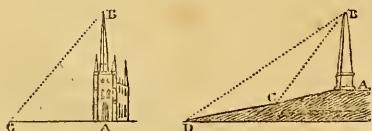

Or thus, by the geometrical square. Which consists of a plain piece of board, a foot square, one of the sides of which, as $g\cdot f$, is divided into a number of equal parts, and having a plumb line suspended at the angular point e , with two sights or a telescope placed on the side $d\cdot e$; and then the whole fixed to a stand at d . At any place, as at c , fix the stand, and turn the square about the centre of motion, d , till the eye there see the top of the object through the sights or telescope on the side $d\cdot e$ of the square, and note the number of divisions cut off the other side by the plumb line $e\cdot g$: then, by similar triangles, as $ef : fg :: de : hb$; to which add ah or cd , for the whole height ab . If the side $g\cdot f$ be divided into 100 equal parts, we have only to multiply the length of dh in feet by the number of parts cut off by the plumb line, and to cut off two figures from the product for decimals; and we shall have the height of bh in feet.

To measure the altitude of an accessible object trigonometrically. At any convenient station, c , with a quadrant, theodolite, or other graduated instrument, observe the angle of elevation acb above the horizontal line ac : and measure the distance ac . Then, a being a right angle, it will be, as radius is to the tangent of the angle c , so is ac to ab sought.

If ac be not horizontal, but an inclined plane; then the angle above it must be observed at two stations c and d in a right line, and the distances ac , cd both measured. Then, from the angle c take the angle bd , and there remains the angle cbd ; hence in the triangle bcd , are given the angles and the side dc , to find the side cb ; and then in the triangle abc , are given the two sides ca and cb , with the included angle c , to find the third side ab .

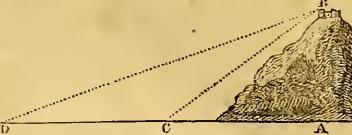

Or thus, measure only the distance ac , and the angles a and c : then, in the triangle abc , are given all the angles and the side ac , to find the side ab .

To measure the altitude of an inaccessible object, as a hill, cloud, or other body. This is commonly done, by observing the angle of its altitude at two stations, and measuring the distance between them. Thus, for the height ab of a hill, measure the distance cd at the foot of it, and observe the quantity of the two angles c and d .

Then, from the angle c taking the angle d , leaves the angle cbd ; hence

As sine $\angle cbd$: sine $\angle d :: cd : cb$; and
As rad. : sine $\angle acb :: cb : ab$, the altitude.

And for a balloon, or cloud, or other moveable object c , let two observers at a and b , in the same plane with c , take at the same time the angles a and b , and measure the distance ab between them; then calculate the altitude cp exactly as in the last example.

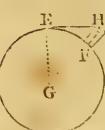

It must however be by mere accident that a , b , and c , are in the same vertical plane; and consequently this method, though it be true in theory, is of no use in practice: we will therefore show how the altitude may be obtained when the observers are not in a plane with the object.

In this case, there must be three observers, who take the angle of elevation at the same instant, being at given distances from each other in the same right line, as at a , b , and c , in the annexed figure; now admitting those three angles to be known, it is required to find the altitude of the balloon.

Demit the perpendicular dp to the horizontal plane acp , and draw the other lines as in the figure. Make t , t' , t'' , represent respectively the nat. cotan. of the angles observed at a , b , and c ; also put $ab = a$, $bc = b$, and $ac = c$; and call $dp = x$. Then $ap = tx$, $bp = t'x$, and $cp = t''x$: hence from the common principles of geometry we find $dp = \sqrt{\frac{t^2 - t'^2}{a^2 + b^2 - c^2}} a$ for the altitude sought. If $\angle a = \angle b$, then $dp = \sqrt{\frac{ac}{t^2 - t'^2}}$

if $\angle b = \angle c$, then $dp = \sqrt{\frac{ac}{t^2 - t''^2}}$; and if $a = b$, then will $dp = \sqrt{\frac{t^2 - t''^2}{2t^2 - t^2 + t''^2}}$.

To find the height of an object, by knowing the utmost distance at which its top can be just seen in the horizon. As, suppose the top h of a tower fhi can be just seen from e when the distance ef is 25 miles, supposing the circumference of the earth to be 25000 miles, or the radius 3979 miles or 21009120 feet. First, as 25000 : 25 : 360° : 21' 36" equal to the angle g ; then as radius : sec. $\angle g :: eg : en$, which will be found to be 21009536 feet; from which take eg or er , and there remains 416 feet, for rn the height of the tower sought.— Or rather thus, as 10000000 radius : 198 = sec. $\angle g$ — radius : 21009120 = $eg : 416 = rn$, as before.

Or the same may be found easier thus: The horizon dips nearly 8 inches or $\frac{2}{3}$ of a foot at the distance of 1 mile, and according to the square of the distance for other distances; therefore as 1^2 or 1 : 25^2 or 625 :: $\frac{2}{3}$: $\frac{2}{3}$ of 625 or 416 feet, the same as before.

Or conversely, to find the distance EF , from the known height FN : Here $\frac{2}{3} : 1$, or as $2 : 3 : 416 : 625$, the square root of which gives 25 miles, for the distance EF . That is, in general, take the square root of $\frac{2}{3}$ of the altitude, in feet, for the distance in miles.

There is a very easy method of taking great terrestrial altitudes, such as mountains, or the heights to which balloons ascend, &c, by means of the difference between the heights of the mercury in the barometer observed at the bottom and top of the same. Which see under the article BAROMETER.

ALTITUDE of the Eye, in Perspective, is a right line let fall from the eye, perpendicular to the geometrical plane.

ALTITUDE, in Astronomy, is the arch of a vertical circle, measuring the height of the sun, moon, star, or other celestial object, above the horizon.

This altitude may be either *true* or *apparent*. The apparent altitude, is that which appears by sensible observations, made at any place on the surface of the earth. And the true altitude, is that which results by correcting the apparent, on account of refraction and parallax.

The quantity of the refraction is different at different altitudes; and the quantity of the parallax is different according to the distance of the different luminaries: in the fixed stars, this is too small to be observed; in the sun, it is but about $\frac{3}{4}$ seconds; but in the moon it is about 52 minutes.

Altitudes are observed by a quadrant, or sextant, or by the shadow of a gnomon or high pole, and by various other ways, as may be seen in most books of astronomy.

Meridian Altitude, is an arch of the meridian, intercepted between any point in it and the horizon. So, if HO be the horizon, and $HEZO$ the meridian; then the arch HE , or the angle HCE , is the meridian altitude of an object in the meridian at the point E .

Altitude, or elevation, of the Pole, is the angle OCP , or arch OP of the meridian, intercepted between the horizon and pole P .

This is equal to the latitude of the place; and it may be found by observing the meridian altitude of the polar star, when it is both above and below the pole, and taking half the sum, when corrected on account of refraction. Or the same may be found by the declination and meridian altitude of the sun.

Altitude, or elevation, of the equator, is the angle HCE , or arch HE of the meridian, between the horizon and the equator at E ; and it is equal to zp the co-latitude of the place.

Altitude of the Tropics, the same as what is otherwise called the solstitial altitude of the sun, or his meridian altitude when in the solstitial points.

Altitude, or height, of the horizon, or of stars, &c, seen in it, is the quantity by which it is raised by refraction.

Refraction of Altitude, is an arch of a vertical circle,

by which the true altitude of the moon, or a star, or other object, is increased by means of the refraction; and is different at different altitudes, being nothing in the zenith, and greatest at the horizon, where it is about 3°.

Parallax of Altitude, is an arch of a vertical circle, by which the true altitude, observed at the centre of the earth, exceeds that which is observed on the surface; or the difference between the angles DLM and $D'M$ of altitude there; and is equal to the angle IDL , formed at the moon or other body, and subtended by the radius DL of the earth.

It is evident that this angle is less, as the luminary is farther distant from the earth; and also less, for any one luminary, as it is higher above the horizon; being greatest there, and nothing in the zenith.

Altitude of the Nonagesimal, is the altitude of the 90th degree of the ecliptic, counted upon it from where it cuts the horizon, or of the middle or highest point of it which is above the horizon, at any time; and is equal to the angle made by the ecliptic and horizon where they intersect at that time.

Altitude of the cone of the earth's or moon's shadow, the height of the shadow of the body, made by the sun, and measured from the centre of the body. To find it, say, As the tangent of the angle of the sun's apparent semidiameter, is to radius, so is 1 to a 4th proportional, which will be the height of the shadow, in semidiameters of the body.

So, the greatest height of the earth's shadow, is 217 $\frac{8}{9}$ semidiameters of the earth, when the sun is at his greatest distance, or his semidiameter subtends an angle of about 15° 47"; and the height of the same is 210 $\frac{7}{9}$ semidiameters of the earth, when the sun is nearest the earth, or when his semidiameter is about 16° 19"—And proportionally between these limits, for the intermediate distances or semidiameters of the sun.

The altitudes of the shadows of the earth and moon, are nearly as 11 to 3, the proportion of their diameters.

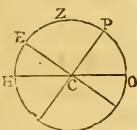

Altitude of motion, is a term used by Dr. Wallis, for the measure of any motion, estimated in the line of direction of the moving force.

Altitude, in speaking of fluids, is more frequently expressed by the term *depth*. The pressure of fluids, in every direction, is in proportion to their altitude or depth. And on this principle is constructed the sea-gage, for finding the depth of the water of the ocean. See GAGE.

Altitude of the mercury, in the barometer and thermometer, is marked by degrees, or equal divisions, placed by the side of the tube of those instruments.

The altitude of the barometer, or of the mercury in its tube, at London, is usually comprised between the limits of 28 and 31 inches; and the mean height, observed for every day in several years, is found nearly 29 $\frac{8}{9}$ inches.

Altitude of the pyramids in Egypt, was measured so long since as the time of Thales, which he effected by means of their shadow, and that of a pole set upright beside them, making the altitudes of the pole and pyramid proportional to the lengths of their shadows. Plutarch has given an account of the manner of this operation, which is one of the first geometrical observations we have an exact account of.

ALTITUDE, *circles of, parallels of, quadrant of, &c.* See the respective words.

Equal ALTITUDE Instrument, is an instrument used to observe a celestial object, when it has the same or an equal altitude, on both sides of the meridian, or before and after it passes the meridian: an instrument very useful in adjusting clocks, &c, and for comparing equal and apparent time.

AMALGAM, in Chemistry and the Arts, a mixture or alloy of mercury with any of the other metals.—For a description of the amalgam used by electricians, and the method of preparing it, see **ELECTRICITY**.

AMBIENT, encompassing round about; as the bodies which are placed round any other body, are called ambient bodies, and sometimes circum-ambient bodies; and the whole mass of the air or atmosphere, because it compasses all things on the face of the earth, is called the ambient air.

AMBIGENAL Hyperbola, a name given by Newton, in his *Enumeration linearum tertii ordinis*, to one of the triple hyperbolæ EGF of the second order, having one of its infinite legs, as EC , falling within the angle ACD , formed by the asymptotes AC , CD , and the other leg GF falling without that angle.

AMBIT, *of a figure*, in Geometry, is the perimeter, or line, or sum of the lines, by which the figure is bounded.

AMBLIGON, or **AMBLIGONAL**, in Geometry, signifies obtuse-angular, as a triangle which has one of its angles obtuse, or consisting of more than 90 degrees.

AMICABLE numbers, denote pairs of numbers, of which each of them is mutually equal to the sum of all the aliquot parts of the other. So the first or least pair of amicable numbers are 220 and 284; all the aliquot parts of which, with their sums, are as follow, viz, of 220, they are 1, 2, 4, 5, 10, 11, 20, 22, 44, 55, 110, their sum being 284; of 284, they are 1, 2, 4, 71, 142, and their sum is 220.

The 2d pair of amicable numbers are 6232 and 6368, which have the same properties.

The 3d pair of amicable numbers are 17296 and 18416, which have also the same property as above.

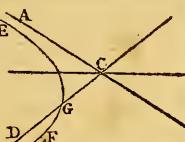

And the 4th pair of amicable numbers are 9363584 and 9437056.

The 1st, 3d, and 4th pairs of amicable numbers were found out by F. Schooten, sect. 9 of his *Exercitationes Mathematicæ*, who I believe first gave the name of *amicable* to such numbers, though their properties it seems had before been treated of by Rudolphus, Descartes, and others.

To find the first pair, Schooten puts $4x$ and $4yz$, or a^2x and a^2yz for the two numbers, where $a = 2$; then making each of these equal to the sum of the aliquot parts of the other, gives two equations, from which are found the values of x and z ; and consequently, assuming a proper value for y , the two amicable numbers themselves $4x$ and $4yz$.

In like manner for the other pairs of such numbers; in which he finds it necessary to assume $16x$ and $16yz$ or a^3x and a^3yz for the 3d pair, and $128x$ and $128yz$ or a^4x and a^4yz for the 4th pair.

Schooten then gives this practical rule, from Descartes, for finding amicable numbers, viz, Assume the number 2,

or some power of the number 2, such that if unity or 1 be subtracted from each of these three following quantities, viz;

from three times the assumed number,
also from six times the assumed number,

and from 18 times the square of the assumed number,
the three remainders may be all primes; then the last prime number being multiplied by double the assumed number, the product will be one of the amicable numbers sought; and the sum of its aliquot parts will be the other. That is, if a be put = the number 2, and a some integer number, such that $3a^n - 1$, and $6a^n - 1$, and $18a^{2n} - 1$ be all three prime numbers; then is $(18a^{2n} - 1) \times 2a^n$ one of the amicable numbers; and the sum of its aliquot parts is the other.

Or this rule may be otherwise expressed thus. Suppose a and b are the pairs of amicable numbers sought; then find such a power of 2, that is, $a = 2^n$, such that $3a - 1 = b$, $6a - 1 = c$, $18a^2 - 1 = d$, the numbers b , c and d may be primes; then will the numbers sought be $a = 2^{n+1}d$, and $b = 2^{n+2}bc$.

The demonstration of which rule is as follows. Let f_A represent the sum of the divisors of A , and f_B the sum of the divisors of B , the whole values of A and B not being comprised, then since $1 + 2^1 + 2^2 + 2^3 + \dots + 2^{n+\frac{1}{2}} = 2^{n+2} - 1$, we shall have $f_A = (2^{n+2} - 1) \cdot (1 + d) - 2^{n+1} \cdot d = (4a - 1)18a^2 - 2a(18a^2 - 1) = b$, and $f_B = (2^{n+2} - 1) \cdot (1 + b) \cdot (1 + c) - 2^{n+1} \cdot bc = (4a - 1) \cdot 18a^2 - 2a(3a - 1) \cdot (6a - 1) = a$, as is evident; because $(1 + 2^1 + 2^2 + \dots + 2^{n+1}) \cdot (d + 1)$ will be the sum of all the divisors of A ; and in the same manner $(1 + 2^1 + 2^2 + \dots + 2^{n+1}) \cdot (b + 1) \cdot (c + 1)$ is the sum of all the divisors of B .

Mr. John Gough has lately investigated some properties of these numbers, especially of the Cartesian form, where ax and ayz are amicable numbers, consisting of a common measure a , multiplied by the primes x, y, z . See Leybourn's Math. Repos. n^o. 7, n. s.

AMONTONS (WILLIAM), an ingenious French experimental philosopher, was born in Normandy the 31st of August 1663. While at the grammar-school, he by sickness contracted a deafness that almost excluded him from the conversation of mankind. In this situation he applied himself to the study of geometry and mechanics; with which he was so delighted, that it is said he refused to try any remedy for his disorder, either because he deemed it incurable, or because it increased his attention to his studies. Among other objects of his study, were the arts of drawing, of land-surveying, and of building; and shortly after he acquired some knowledge of those more sublime laws by which the universe is regulated. He studied with great care the nature of barometers and thermometers; and wrote his treatise of Observations and Experiments concerning a new Hour-glass, and concerning Barometers, Thermometers, and Hygoscopes; as also some pieces in the Journal des Savans. In 1687, he presented a new hygroscope to the Academy of Sciences, which was much approved. He recommended a method of conveying intelligence to a great distance in a short space of time: this was by making signals from one person to another, placed at great distances from each other as they could see the signals by means of telescopes. When the Royal Academy

was now regulated in 1699, Amontons was chosen a member of it, as an élève under the third Astronomer; and he read there his New Theory of Friction, in which he happily cleared up an important object in mechanics. In fact he had a particular genius for making experiments: his notions were just and delicate: and he knew how to prevent the inconveniences of his new inventions, and had a wonderful skill in executing them. He died of an inflammation in his bowels, the 11th of October 1705, being only 42 years of age.

The eulogies of Amontons may be seen in the volume of the Memoirs of the Academy of Sciences for the year 1705, Hist. pa. 150. And his pieces contained in the different volumes of that work, which are pretty numerous, and on various subjects, as the air, action of fire, barometers, thermometers, hygrometers, friction, machines, heat, cold, rarefactions, pumps, &c, may be seen in the volumes for the years 1696, 1699, 1702, 1703, 1704, and 1705.

AMPHISCIL, or **AMPHISCANIANS**, are the people who inhabit the torrid zone; which are so called, because they have their shadow at noon turned sometimes one way and sometimes another, namely, at one time of the year towards the north, and at the other towards the south.

AMPLITUDE, in Gunnery, the range of a projectile, or the right line upon the ground subtending the curvilinear path in which it moves.

AMPLITUDE, in Astronomy, is an arch of the horizon, intercepted between the true east or west point, and the centre of the sun or a star at its rising or setting: so that the amplitude is of two kinds; ortive or eastern, and occiduous' or western. Each of these amplitudes is also either northern or southern, according as the point of rising or setting is in the northern or southern part of the horizon: and the complement of the amplitude, or the arch of distance of the point of rising or setting, from the north or south point of the horizon, is the azimuth.

The amplitude is of use in navigation, to find the variation of the compass or magnetic needle. And the rule to find it is this: As the cosine of the latitude is to radius, so is the sine of the sun's or star's declination, to the sine of the amplitude. So in the latitude of London, viz, $51^{\circ} 31'$, when the sun's declination is $23^{\circ} 28'$; then $\cos. 51^{\circ} 31'$ the lat. - - - 97939907
 $\sin. 23^{\circ} 28'$ the decl. - + 96001181
 $\sin. 39^{\circ} 47'$ the ampl. - - 98061274

That is, the sun then rises or sets $39^{\circ} 47'$ from the east or west point, to the north or south according as the declination is north or south.

MAGNETICAL AMPLITUDE, is an arch of the horizon, contained between the sun or star, at the rising or setting, and the magnetical east or west point of the horizon, pointed out by the magnetical compass, or the amplitude or azimuth compass. And the difference between this magnetical amplitude, so observed, and the true amplitude, as computed in the last article, is the variation of the compass.

So if, for instance, the magnetical amplitude be observed, by the compass, to be $61^{\circ} 47'$, at the time when it is computed to be - - $39^{\circ} 47'$, then the difference - - $22^{\circ} 0'$ is the variation west.

ANABIBAZON, a name sometimes given to the dragon's tail, or northern node of the moon.

ANACAMPTICS, or the science of the reflections of sounds, frequently used in reference to echoes, which are

said to be sounds produced anacampitically, or by reflection. And in this sense it was used by the ancients for that part of optics which is otherwise called Catoptrics.

ANACHRONISM, in Chronology, an error in computation of time, by which an event is placed earlier than it really happened. Such is that of Virgil, who makes Dido to reign at Carthage in the time of Æneas, though, in reality, she did not arrive in Africa till 300 years after the taking of Troy.

An error on the other side, by which a fact is placed later, or lower than it should be, is called a parachronism. But in common use, this distinction, though proper, is not attended to; and the word anachronism is used indifferently for the mistake on both sides.

ANACLASTICS, or **ANACLATICS**, an ancient name for that part of optics which considers refracted light; being the same as what is more usually called dioptrics. See the Compendium of Ambrosius Rhodius, lib. 3. Opticæ, pa. 384. & seq.

ANACLASTIC CURVES, a name given by M. de Mairan to certain apparent curves formed at the bottom of a vessel full of water, to an eye placed in the air; or the vault of the heavens, seen by refraction through the atmosphere. M. de Mairan determines these curves by a principle not admitted by all authors; but Dr. Barrow, at the end of his Optics, determines the same curves by other principles.

ANALEMMA, a planisphere, or projection of the sphere, orthographically made on the plane of the meridian, by perpendiculars from every point of that plane, the eye supposed to be at an infinite distance, and in the east or west point of the horizon. In this projection, the solstitial colure, and all its parallels, are projected into concentric circles, equal to the real circles in the sphere; and all circles whose planes pass through the eye, as the horizon and its parallels, are projected into right lines equal to their diameters; but all oblique circles are projected into ellipses, having the diameter of the circle for the transverse axis. This instrument, having the furniture drawn on a plate of wood or brass, with an horizon fitted to it, is used for resolving many astronomical problems; as the time of the sun's rising and setting, the length and hour of the day, &c. It is also useful in dialling, for laying down the signs of the zodiac, with the lengths of days, and other matters of furniture, upon dials.

The oldest treatise we have on the analemma, was written by Ptolemy, which was printed at Rome 1562, with a commentary by F. Commandine. Pappus also treated of the same. Since that time, many other authors have treated very well of the analemma; as Aguilonius, Taquet, Dechales, Witty, &c.

ANALOGY, the same as proportion, or equality, or similitude of ratios. Which see.

ANALYSIS, is, generally, the resolution of any thing into its component parts, in order to discover it or its composition. And in mathematics it is properly the method of resolving problems, by reducing them to equations. Analysis may be distinguished into the ancient and the modern.

The ancient analysis, as described by Pappus, is the method of proceeding from the thing sought as taken for granted, through its consequences, to something that is really granted or known; in which sense it is the reverse of synthesis or composition, in which we lay that down

first which was the last step of the analysis, and tracing the steps of the analysis back, making that antecedent here which was consequent there, till we arrive at the thing sought, which was taken or assumed as granted in the first step of the analysis. This chiefly respected geometrical inquiries.

The principal authors on the ancient analysis, as recounted by Pappus, in the 7th book of his Mathematical Collections, are Euclid in his Data, Porismata, et de Loci ad Superficiem; Apollonius de Sectione Rationalis, de Sectione Spatii, de Tractionibus, de Inclinationibus, de Loci Planis, et de Sectionibus Conicis; Aristaeus, de Loci Solidis; and Eratosthenes, de Mediis Proportionalibus: from which Pappus gives many examples in the same book. To these authors we may add Pappus himself. The same sort of analysis has also been well cultivated by many of the moderns; as Fermat, Viviani, Ghetaldus, Snellius, Huygens, Simson, Stewart, Lawson, Playfair, Leslie, &c, and more especially Hugo d'Omerique, in his Analysis Geometrica, in which he has endeavoured to restore the analysis of the ancients. And on this head, Dr. Pemberton tells us, "that sir Isaac Newton used to censure himself for not following the ancients more closely than he did; and spoke with regret of his mistake, at the beginning of his mathematical studies, in applying himself to the works of Descartes, and other algebraical writers, before he had considered the Elements of Euclid with that attention so excellent a writer deserves; that he highly approved the laudable attempt of Hugo d'Omerique to restore the ancient analysis."

In the application of the ancient analysis in geometrical problems, every thing cannot be brought within strict rules; nor any invariable directions given, by which we may succeed in all cases; but some previous preparation is necessary, a kind of mental contrivance and construction, to form a connexion between the data and quæsita, which must be left to every one's judgment to find out; being various, according to the various nature of the problems proposed. Right lines must be drawn in particular directions, or of particular magnitudes; bisecting perhaps a given angle, or perpendicular to a given line; or perhaps tangents must be drawn to a given curve, from a given point; or circles described from a given centre, with a given radius, or touching given lines, or other circles; or such-like operations. Whoever is conversant with the works of Archimedes, Apollonius, or Pappus, well knows that they founded their analysis on some such previous operations; and the great skill of the analyst consists in discovering the most proper affections on which to found his analysis; for the same problem may often be effected in many different ways: of which it may be proper to give here an example or two. Let there be taken, for instance, this problem, which is the 155th prop. of the 7th book of Pappus.

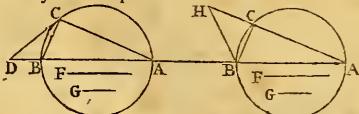

From the extremities of the base AB , of a given segment of a circle, required to draw two lines AC , BC , meeting at a point C in the circumference, so that they shall have a given ratio to each other, suppose that of F to G .

The solution of this problem, as given by Pappus, is thus,

ANALYSIS.

Suppose the thing done, and that the point C is found: and let CD be drawn a tangent to the circle at C , and meeting the line AB produced in the point D . Now by the

hypothesis $AC : BC :: F : G$, and also $AC^2 : BC^2 :: DA : DB$, as may be thus proved.

Since DC touches the circle, and BC cuts it, the angle BCD is equal to BAC by Euc. iii 32; also the angle D is common to both the triangles DCA , DCB ; these are therefore similar, and so, by vi 4, $DA : DC :: DB : DC$, and hence $DA^2 : DC^2 :: DA : DB$ by cor. vi 20. But also, by vi 4, $DA : AC :: DC : CB$, and by permutation $DA : DC :: AC : BC$, or $DA^2 : DC^2 :: AC^2 : BC^2$; and hence, by equality, $AC^2 : BC^2 :: DA : DB$.

But the ratio of AC^2 to BC^2 is given, because the ratio of AC to BC is given, and consequently that of DA to DB is given. Now since the ratio of DA to DB is given, therefore also, by Data vi, that of DA to AB , and hence, by Data ii, DA is given in magnitude.

And here the analysis properly ends. For it having been shown that AB is given, or that a point D may be found in AB produced, such, that a tangent being drawn from it to the circumference, the point of contact will be the point sought; we may now begin the composition, or synthetical demonstration; which must be done by finding the point D , or laying down the line AB , which, it was affirmed, was given, in the last step of the analysis.

SYNTHESIS.

Construction. Make as $F^2 : G^2 :: AD : DB$, (which may be done, since AB is given, by making it as $F^2 : G^2 :: AB : DB$, and then by composition it will be as $F^2 : G^2 :: AD : DB$); then from the point D , thus found, draw a tangent to the circle, and from the point of contact c drawing ca and cb , the thing is done.

Demonstration. Since, by the constr. $F^2 : G^2 :: AD : DB$, and also $AD : DB :: AC^2 : BC^2$, which has been already demonstrated in the analysis, and might be here proved in the same manner. Therefore $F^2 : G^2 :: AC^2 : BC^2$, and consequently $F : G :: AC : BC$. Q. E. D.

Here we see an instance of the method of resolution and composition, as it was practised by the ancients, the solution here given being that of Pappus himself. But as the method of referring and reducing every thing to the Data, and constantly quoting the same, may appear now to be tedious and troublesome: and indeed it is unnecessary to those who have already made themselves masters of the substance of that valuable book of Euclid, and have by practice and experience acquired a facility of reasoning in such matters: I shall therefore now show how we may abate something of the rigour and strict form of the ancient method of solution, without diminishing any part of its admirable elegance and perspicuity. And this may be done by means of another solution, of the many more which might be given, of the same problem, as follows.

ANALYSIS.

Let us again suppose that the thing is done, viz.: $AC : BC :: F : G$, and let there be drawn AB making the angle A equal to the angle ACB , and meeting AC produced in H . Then, the angle A being also common, the two triangles ABC and AHB are equiangular, and therefore, by vi 4, $AC : BC :: AB : BH$, in a given ratio; and, as

being given, therefore BH is given in position and magnitude.

SYNTHESIS.

Construction. Draw BH making the angle ABH equal to that which may be contained in the given segment, and take AB to BH in the given ratio of r to c . Draw ACH , and BC .

Demonstration. The triangles ABC , ABH are equiangular, therefore, vi 4, $AC : CB :: AB : BH$, which is the given ratio by construction.

Modern ANALYSIS, consists chiefly of algebra, arithmetic of infinites, infinite series, increments, fluxions, &c; of each of which a particular account may be seen under their respective articles.

These form a kind of arithmetical and symbolical analysis, depending partly on modes of arithmetical computation, partly on rules peculiar to the symbols made use of, and partly on rules drawn from the nature and species of the quantities they represent, or from the modes of their existence or generation.

The modern analysis is a general instrument, by which the finest inventions, and the greatest improvements, have been made in mathematics and philosophy, for two centuries past. It furnishes the most perfect examples of the manner in which the art of reasoning should be employed; it gives to the mind a wonderful skill for discovering things unknown, by means of a small number that are given; and by employing short and easy symbols for expressing ideas, it presents to the understanding things which otherwise would seem to lie above its sphere. By this means, geometrical demonstrations may be greatly abridged; a long train of arguments, in which the mind cannot, without the greatest effort of attention, discover the connexion of ideas, is converted into visible symbols; and the various operations which they require, are simply effected by the combination of those symbols. And, what is still more extraordinary, by this artifice, a great number of truths are often expressed in one line only: instead of which, by following the ordinary way of explanation and demonstration, the same truths would occupy whole pages or volumes. And thus, by the bare contemplation of one line of calculation, we may understand in a short time whole sciences, which otherwise could hardly be comprehended in several years.

It is true that Newton, who best knew all the advantages of analysis in geometry and other sciences, laments, in several parts of his works, that the study of the ancient geometry is abandoned or neglected. And indeed the method employed by the ancients in their geometrical writings, is commonly regarded as more rigorous than that of the modern analysis: and though it be greatly inferior to the latter, in point of dispatch and facility of invention; it is nevertheless highly useful in strengthening the mind, improving the reasoning faculties, and in accustoming the young mathematician to a pure, clear, and accurate mode of investigation and demonstration, though by a long and laboured process, which he would with difficulty have submitted to if his taste had before been vitiated, as it were, by the more piquant sweets of the modern analysis. And it is principally on this that the complaints of Newton are founded, who feared lest by the too early and frequent use of the modern analysis, the science of geometry should lose that rigour and purity which characterise its investigations, and the mind become debilitated by the facility of our analysis. This great man

was therefore well founded, in recommending, to a certain extent, the study of the ancient geometers: for, their demonstrations being more difficult, give more exercise to the mind, accustom it to a closer application, give it a greater scope, and habituate it to patience and resolution, so necessary for making discoveries. But this is the only or principal advantage from it; for if we should look no farther than the method of the ancients, it is probable that, even with the best genius, we should have made but few or small discoveries, in comparison with those obtained by means of the modern analysis. And even with regard to the advantage given to investigations made in the manner of the ancients, namely of being more rigorous, it may perhaps be doubted whether this pretension be well founded. For, to instance in those of Newton himself, though his demonstrations be managed in the manner of the ancients; yet at the same time it is evident that he investigates his theorems by a method different from that employed in the demonstrations, which are commonly analytical calculations, disguised by substituting the name of lines for their algebraical value: and though it be true that his demonstrations are rigorous, it is no less so that they would be the same when translated and delivered in algebraic language; and what difference can it make in this respect, whether we call a line A_B , or denote it by the algebraic character a ? Indeed this last designation has this peculiarity, that when all the lines are denoted by algebraic characters, many operations can be performed upon them, without thinking of the lines or the figure. And this circumstance proves of no small advantage: the mind is relieved, and spared as much as possible, that its whole force may be employed in overcoming the natural difficulty of the problem alone.

Upon the whole therefore, the state of the comparison seems to be this; That the method of the ancients is fittest to begin our studies with, to form the mind and to establish proper habits; and that of the moderns to succeed, by extending our views beyond the present limits, and enabling us to make new discoveries and improvements.

Analysis is divided, with respect to its object, into that of finites, and that of infinites.

Analysis of finite quantities, is what is otherwise called algebra, or specious arithmetic.

Analysis of infinites, called also the *new analysis*, is that which is concerned in calculating the relations of quantities which are considered as infinite, or infinitely small; one of its chief branches being the method of fluxions, or the differential calculus. And the great advantage of the modern mathematicians over the ancients, arises chiefly from the use of this modern analysis.

ANALYSIS OF POWERS, is the same as resolving them into their roots, and is otherwise called Evolution.

ANALYSIS OF CURVE LINES, shows their constitution, nature, and properties, their points of inflection, station, retrogradation, variation, &c.

ANALYST, a person who analyses something, or makes use of the analytical method. In mathematics it is a person skilled in algebra, or in the mathematical analysis in general.

ANALYST, the title of an ingenious, though sophistical book, written by the celebrated Dr. Berkeley, against the doctrine of fluxions.

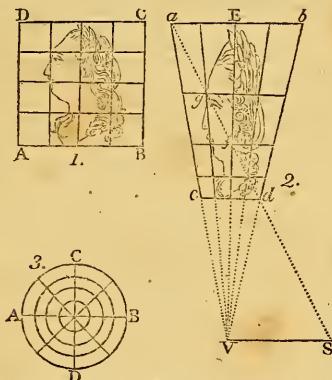

ANALYTIC, or *ANALYTICAL*, something belonging to, or partaking of, the nature of analysis; or performed by the method of analysis.

Thus we say analytical demonstration, analytical enquiry, analytical table or scheme, analytical method, &c. The analytical stands opposed to the synthetical, or that which proceeds by the way of synthesis.

ANALYTICS, the science, or doctrine, and use of analysis.

ANAMORPHOSIS, in perspective and painting, a monstrous projection; or a representation of some image, either on a plane or curve surface, deformed or distorted; but which in a certain point of view shall appear regular, and drawn in just proportion.

To construct an Anamorphosis, or monstrous projection on a plane.—Draw the square $ABCD$ (fig. 1), of any size at pleasure, and divide it by crossing lines into a number of areolæ or smaller squares: and then in this square, or reticule, called also the craticular prototype, draw the regular image which is to be distorted.—Or, about any image, proposed to be distorted, draw a reticle of small squares.

Then draw the line ab (fig. 2) equal to AB , dividing it into the same number of equal parts, as the side of the prototype AB ; and on its middle point E erect the perpendicular ev , as also vs perpendicular to ev , making ev so much the longer, and vs so much the shorter, as it is intended the image shall be more distorted. From each of the points of division draw right lines to the point v , and draw the right line as . Lastly, through the points $c, e, f, g, \&c.$, draw lines parallel to ab : So shall $abcd$ be the space upon which the monstrous projection is to be drawn; which is called the craticular ectype.

Then, in every areola, or small trapezium, of the space $abcd$, draw what appears contained in the corresponding areola of the original space $ABCD$: so shall there be produced a deformed image in the space $abcd$, which yet will appear in just proportion to an eye distant from it the length of ev , and raised above it by a height equal to vs .

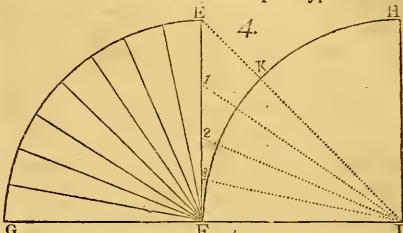

It will be amusing to contrive it so, that the deformed image may not represent a mere chaos, but some certain figure: thus, a river with soldiers, waggons, and other objects on the side of it, have been so drawn and distorted, that when viewed by an eye at S , it appeared like the face of a satyr.

An image may also be distorted mechanically, by perforating it through in several places with a fine pin; then, placing it against a candle or lamp, observe where the rays,

which pass through these small holes, fall on any plane or curve superficies; for they will give the correspondent point of the image deformed, and by means of which the deformation may be completed.

To draw an Anamorphosis on the convex surface of a cone. It appears from the construction above, that we have only to make a craticular ectype on the surface of the cone, which may appear equal to the craticular prototype, to an eye placed at a proper height above the vertex of the cone. Hence,

Let the base, or circumference, $ABCD$, of the cone (fig. 3) be divided by radii into any number of equal parts; and let some one radius be likewise divided into equal parts; then through each point of division draw concentric circles: so shall the craticular prototype be formed.

With double the diameter AB , as a radius; describe the quadrant EGF (fig. 4) so as the arch eg be equal to the whole periphery; then this quadrant, being plied or bent round, will form the superficies of a cone, whose base is the circle.

Next divide the arch EG into the same number of equal parts as the craticular prototype is divided into; and draw radii from all the points of division. Produce ge to t , so that rt be equal to re ; from the centre r , with the radius te , describe the quadrant FKH ; and draw the right line te . Then divide the arch KF into the same number of equal parts as the radius of the craticular prototype is divided into; and from the centre r draw radii through all the points of division, meeting er in 1, 2, 3, &c. Lastly, from the centre r , with the radii $r1, r2, r3, \&c.$, describe concentric circles. So will the craticular ectype be formed, whose areolas will appear equal to each other.

Hence, what is delineated in every areola of the craticular prototype, being transferred into the areolas of the craticular ectype, the images will be distorted or deformed; and yet they will appear in just proportion to an eye elevated above the vertex at a height equal to the height of the cone itself.

If the chords of the quadrants be drawn in the craticular prototype, and chords of each of the 4th parts in the craticular ectype, every thing else remaining the same, there will be obtained the craticular ectype in a quadrangular pyramid.

And hence it will be easy to deform an image, in any other pyramid, whose base is any regular polygon.

Because the illusion is more perfect when the eye, by the contiguous objects, cannot estimate the distance of the parts of the deformed image, it is therefore proper to view it through a small hole.

Anamorphoses, or monstrous images, may also be made to appear in their natural shape and just proportions, by means of mirrors of certain shapes, from which those

images are reflected again; and then they are said to be reformed. For farther particulars, see Wolfius's *Catoptrics* and *Dioptrics*, and some other optical authors.

ANASTROUS signs, in Astronomy, a name given to the duodecatemoria, or the 12 portions of the ecliptic, which the signs possessed anciently, but have since deserted by the precession of the equinox.

ANAXAGORAS, one of the most celebrated philosophers among the ancients. He was born at Clazomenae in Ionia, about the 70th Olympiad. He was a disciple of Anaximenes; and he gave up his patrimony, to be more at leisure for the study of philosophy, giving lectures in that science at Athens. Being persecuted in this place, and at last banished from it, he opened a school at Lampasacum, where he was greatly honoured during his life, and still more after his death, statues having been erected to his memory. It is said he made predictions relative to the phenomena of nature, as earthquakes, &c, upon which he wrote some treatises. His principal tenets may be reduced to the following:—All things were in the beginning confusedly mixed together, without order and without motion. The principle of things is at the same time one and multiplex, which had the name of homeomeries, or similar particles, deprived of life. But there is beside this, from all eternity, another principle, an infinite and incorporeal spirit, who gave motion to these particles; in virtue of which, such as were homogeneous united, and such as were heterogeneous separated according to their different kinds. All things being thus put into motion by the spirit, and every thing being united to such as are similar, those that had a circular motion produced heavenly bodies, the lighter particles ascending, while those that were heavier descended. The rocks of the earth, being drawn up by the whirling force of the air, took fire, and became stars, beneath which the sun and moon took their stations.—It was said he also wrote upon the quadrature of the circle; the treatise on which, Plutarch says, he composed during his imprisonment at Athens.

ANAXIMANDER, a very celebrated Greek philosopher, was born at Miletus in the 42d Olympiad; for, according to Apollodorus, he was 64 years of age in the 2d year of the 58th Olympiad. He was one of the first who publicly taught philosophy, and wrote upon philosophical subjects. He was the kinsman, companion, and disciple of Thales. He wrote also upon the sphere and on geometry, &c. And he carried his researches into nature very far, for the time in which he lived. It is said that he discovered the obliquity of the zodiac; that he first published a geographical table; that he invented the gnomon, and set up the first sun-dial in an open place at Lacedæmon. He taught that infinity of things was the principal and universal element; that this infinite always preserved its unity, but that its parts underwent changes; that all things came from it; and that all were about to return to it. By this obscure and indeterminate principle he probably meant the chaos of other philosophers. He held that the worlds are infinite; that the stars are composed of air and fire, which are carried about in their spheres, and that these spheres are gods; and that the earth is placed in the midst of the universe, as in a common centre. Farther, that infinite worlds were the produce of infinity; and that corruption proceeded from separation.

ANAXIMENES, an eminent Greek philosopher, born at Miletus, the friend, scholar, and successor of Anaxi-

mander. He diffused some degree of light upon the obscurity of his master's system. He made the first principle of things to consist in the air, which he considered as infinite or immense, and to which he ascribed a perpetual motion; that this air was the same as spirit or God, since the divine power resided in it, and agitated it. The stars were as fiery nails in the heavens; the sun a flat plate of fire; the earth an extended flat surface, &c.

ANDERSON (*ALEXANDER*), one of the brightest ornaments of the mathematical world, who flourished about 200 years ago. It appears that he was born at Aberdeen in Scotland, towards the latter part of the 16th century, and he was professor of mathematics at Paris in the early part of the 17th, where he published several ingenious works in geometry and algebra, both of his own, and of his friend Vieta's. He published his

1. “Supplementum Apollonii Redivivi; sive analysis problematis hactenus desiderati ad Apollonii Pergei doctrinam περὶ νευτεῶν, a Marino Ghetaaldo Patrio Ragusino hujusque, non ita pridem restitutam. In qua exhibetur mechanice æquivalutum tertii gradus sive solidarum, in quibus magnitudo omnino data, æquatur homogenea sub altero tantum coefficiente ignoto. Huic subnexa est variiorum problematum practice.” Paris, 1612, in 4to.

2. “*Απίστολη*; Pro Zeteticis Apollonianis problematis a se jam pridem edito in supplemento Apollonii Redivivi. Ad clarissimum et ornatissimum virum Marinum Ghetaldum Patrium Ragusinum. In qua ad ea quea obiter mihi perstrinxit Ghetaldus responderet, et analytices clarius detegitur.” Paris, 1615, in 4to.

3. “Francisci Vieta Fontenacensis de Aequationum Recognitione et Emendatione Tractatus duo.” Paris, 1615, in 4to; with a Dedication, Preface, and an Appendix, by Anderson.

4. “Ad Angularium Sectionum Analyticem Theoremata Καθελικούτερα. A Francisco Vieta Fontenacensi, excogitata, at absque ulla demonstratione ad nos transmissa, jam tandem demonstrationibus confirmata. Opera et studio Alexandri Andersoni Scoti.” Parisii, 1615, in 4to.

5. “Vindiciae Archimedis. Sive, Elenchus Cyclometriae novae, a Philippo Lansbergio nuper edite. Per Alexandrum Andersonum Scotum.” Parisii, 1616, in 4to.

6. “Alexandri Andersoni Scoti Exercitationum Mathematicarum Dicas Prima. Continenas, Quæstionum aliquot, quæ nobilissimorum tum hujus tum veteris ævi, Mathematicorum ingenia exercere, Enodationem.” Parisii, 1619, in 4to.

All these pieces, of this excellent geometer, are replete with the finest specimens of pure geometrical exercises that have perhaps ever been produced by any authors, ancient or modern. So that it is to be lamented that the limits of this work will not admit of giving the full account of all the particulars contained in them, which I had prepared indeed expressly for that purpose. Besides these, I am not aware of any more publications of our author, though perhaps there may have been others. Indeed from the last piece, it fully appears that he had at least written, if not published, another, viz. A treatise on the mensuration of solids, perhaps with a reference to gauging; as, in several problems, where he critically examines the treatise on cask-gauging of Kepler, our author often refers to his own work on stereometry, which I have not learned had ever been published.

Alexander was cousin-german to a Mr. David Anderson, of Finshaugh, a gentleman who also possessed a singular turn for mathematical and mechanical knowledge. This mathematical genius appears to have been hereditary in the family of the Andersons, and from them transmitted to their descendants of the name of Gregory in the same country: the daughter of the said David Anderson having been the mother of the celebrated mathematician James Gregory, and who herself first instructed her son James in the elements of the mathematics, on observing in him, while yet a child, a strong propensity to those sciences.

The time either of the birth or death of our author Alexander, has not come to my knowledge.

ANDERSON (ROBERT), an ingenious mathematician, who flourished in the latter half of the 17th century, and was much noticed and encouraged in those studies by the mathematical John Collins, among others, so often mentioned in the early labours of the Royal Society. Mr. Anderson was not in the profession of mathematics, or of those other branches which it appears he usefully cultivated and improved; but was a silk-weaver by trade, and must have been a person of some consideration and substance, as he was able to make, at his own charge, some thousands of experiments with cannon, for improving the art of gunnery; which he did in a considerable degree, as appears by the tracts on that art which he published, as deduced from those experiments; viz, *The Genuine Use and Effects of the Gun*, in 1674; *To Hit a Mark*, in 1690; and, *To Cut the Rigging, &c.* in 1691, all in 4to. He published also, *Stereometrical Propositions*, variously applicable, but particularly intended for Gauging: in small 8vo, 1668. This little work is an elaborate treatise on the measurement of all kinds of solids that can be generated by the rotation of circles and the conic sections, or the ellipse, hyperbola, and parabola; viz, all spheres, spheroids, conoids, and spindles, &c, with their segments, zones, unguis, &c.

ANDROMEDA, in Astronomy, a constellation of the northern hemisphere, representing the figure of a woman almost naked, her feet at a distance from each other, and her arms extended and chained; being one of the original 48 asterisms, or figures under which the ancients comprehended the stars, as derived to us from the Greeks, who probably had them from the Egyptians or Indians, and who, it is suspected, altered their names, and accompanied them with fabulous stories of their own. According to them, Cepheus, the father of Andromeda, was obliged to give her up to be devoured by a monster, to preserve his kingdom from the plague; but that she was delivered by Perseus, who slew the monster, and espoused her. And the family were all translated by Minerva to heaven, the mother being the constellation Cassiopeia.

She is sometimes called, in Latin, *Persea, Mulier catenata, Virgo devota*, &c. The Arabians, whose religion did not permit them to draw the figure of the human body on any occasion whatever, have changed this constellation into the figure of a sea-calf. Schickard has changed the name for that of the Scripture name Abigail. And Schiller has also changed the figure of the constellation, for that of a sepulchre, and calls it the Holy Sepulchre.

This constellation contains about 27 stars, that are visible to the naked eye; of which the principal are, α Andromeda's head; β in the girdle, and called Mirach or Mizar; γ on the south foot, and named Alamat, and sometimes Alhames.

The number of stars placed in this constellation, by the catalogue of Ptolemy is 23, by that of Tycho Brahe also 23, by that of Hevelius 47, and by that of Flamsteed 66.

ANEMOMETER, an instrument for measuring the force of the wind.

An instrument of this sort, it seems, was first invented by Wolfius; in the year 1708, and first published in his Areometry in 1709, also in the Acta Eruditorum, of the same year; afterwards in his Mathematical Dictionary, and in his Elem. Matheseos. He says he tried the goodness of it, and observes that the internal structure may be preserved, so as to measure the force of running water, or that of men or horses when they draw or pull. The machine consists of sails, A, B, C, like those of a wind-mill, against which the wind blows, and by turning them about raises an arm K with a weight L upon it, to different angles of elevation, shown by the index M, according to the force of the wind. (Plate iii. fig. 3.)

Mr. Leutmann improved on Wolfius's anemometer, by placing the sails horizontal, instead of vertical, which are easier then to move, and turn whatever way the wind blows.

Mr. Benjamin Martin also (Plate iii. fig. 5) improved on the same. He made the axis like the fusee of a watch, having a cord winding upon it, with two weights at the ends, which make always a balance to the force of the wind on the sails. See his Philos. Britan.

And M. D'Ons-en-Bray invented a new anemometer, which of itself expresses on paper, not only the several winds that have blown during the space of 24 hours, and at what hour each began and ended, but also their different velocity. See Mem. Acad. Scien. an. 1734.

In the Philos. Trans., another anemometer is described, in which the wind being supposed to blow directly against a flat side, or board, which moves along the graduated arch of a quadrant, the number of degrees it advances shows the comparative force of the wind.

In the same Transactions, for the year 1766, Mr. Alex. Brice describes a method, successfully practised by him, of measuring the velocity of the wind, by means of that of the shadow of clouds passing over a plane upon the earth.

Also in the same Transactions, for the year 1775, Dr. Lind gives a description of a very ingenious portable Wind-Gauge, by which the force of the wind is easily measured; and which seems to have been suggested by a hint of Dr. Hales, in his Description of Ventilators, pa. 12, and described in the Huictiana, long before Dr. Lind's time. A brief description of the principal parts of it here follows. This simple instrument consists of two glass tubes, AB, CD (Plate iii. fig. 4), which should not be less than 8 or 9 inches long, the bore of each being about $\frac{1}{10}$ of an inch diameter, and connected together by a small bent glass tube ab, only of about $\frac{1}{10}$ of an inch diameter, to check the undulations of the water caused by a sudden gust of wind. On the upper end of the leg AB is fixed at right angles to it a thin metal tube, and having its mouth open to receive the wind blowing horizontally into it. The two tubes, or rather the two branches of the tube, are connected to a steel spindle KL, by slips of brass near the top and bottom, on the sockets of which at e and f, by the wind blowing in at the orifice at F, the whole instrument turns easily about the spindle, which is fixed into a block by a screw in its bottom. When the instru-

ment is used, a quantity of water is poured in, till the tubes are about half full; then exposing the instrument to the wind, by blowing in at the orifice r , it forces the water down lower in the tube AB , and raises it so much higher in the other tube; then the distance between the surfaces of the water in the two tubes, estimated by a scale of inches and parts $h1$, placed by the sides of the tubes, will be the height of a column of water whose weight is equal to the force or momentum of the wind, blowing or striking against an equal base. And as a cubic foot of water weighs 1000 ounces, or $62\frac{1}{2}$ pounds, the 12th part of which is $5\frac{1}{4}$ or $5\frac{1}{2}$ pounds nearly, therefore for every inch the surface of the water is raised, the force of the wind will be equal to so many times $5\frac{1}{2}$ pounds on a square foot. Thus, suppose the water stand 3 inches higher in the one tube, than in the other; then 3 times $5\frac{1}{2}$, or $15\frac{3}{4}$ pounds, is equal to the pressure or force of the wind on the surface of a square foot.

This instrument of Dr. Lind's, measures only the force or momentum of the wind, but not its velocity. However, the velocity of the wind may be deduced from its force so obtained, by help of some experiments performed by me at the Royal Military Academy, in the years 1786, 1787, and 1788; from which it appears that a plane surface of a square foot suffers a resistance of 12 ounces, or $\frac{3}{4}$ of a pound, from the wind, when blowing with a velocity of 20 feet per second; and that the force is nearly as the square of the velocity. Hence then, taking the force of $15\frac{3}{4}$ pounds, above found, for the force of the wind when it sustains 3 inches of water, and taking the square roots of the forces, it will be, as $\sqrt{\frac{3}{4}} : \sqrt{15\frac{3}{4}} :: 20 : 91\frac{1}{2}$ the 4th proportional, that is a velocity of $91\frac{1}{2}$ feet per second, or 62 miles per hour, is the rate or velocity at which the wind blows, when it raises the water 3 inches higher in the one tube than the other. And farther, as the said height is as the force, and the force as the square of the velocity, we shall have the force and velocity, corresponding to several heights of the water in the one tube, above that in the other, as in the following table.

Table of the corresponding height of water, force of the wind on a square foot, and its velocity per hour.

Height of water.	Force of wind.	Velocity of wind per hour.
Inches.	Pounds.	Miles.
0 $\frac{1}{4}$	1'3	18'0
0 $\frac{1}{2}$	2'6	25'6
1	5'2	36'0
2	10'4	50'8
3	15'6	62'0
4	20'8	76'0
5	26'0	89'4
6	31'25	88'0
7	36'5	95'2
8	41'7	101'6
9	46'9	108'0
10	52'1	113'6
11	57'3	119'2
12	62'5	124'0

See also *Wind-Gauge*.

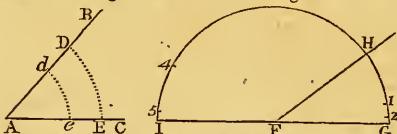

ANEMOSCOPE, is sometimes used to denote a machine invented to foretell the changes of the wind, or weather; and sometimes for an instrument showing by an index what the present direction of the wind is. Of this

latter kind, it seems, was that used by the ancients, as described by Vitruvius; and we have many of them at present in large or public buildings, where an index within a room or hall, points to the name of the quarter from which the wind blows without; which is simply effected by connecting an index to the lower end of the spindle of a weather-cock.

It has been observed that hygoscopes made of cat-gut, or such like, prove very good anemoscopes; seldom failing, by the turning of the index, to foretell the shifting of the wind. See accounts of two different anemoscopes; one by Mr. Pickering, vol. 43 Philos. Trans. the other by Mr. B. Martin, vol. 2 of his Philos. Britan.

Otto Guericke also gave the title anemoscope to a machine invented by him to foretell the change of the weather, as to rain and fair. It consisted of the small wooden figure of a man, which rose and fell in a glass tube, as the atmosphere was more or less heavy. Which was only an application of the common barometer, as shown by M. Couriers in the Acta Erudititorum for 1684.

ANGLE, *Angulus*, in Geometry, the opening or mutual inclination of two lines, or two planes, meeting in a point, called the vertex or angular point. Such as the angle formed by, or between the two lines AB and AC , at the vertex or angular point A .—Also the two lines AB and AC , are called the legs or the sides of the angle.

Angles are sometimes denoted, or named, by the single-letter placed at the angular point, as the angle a ; and sometimes by three letters, as BAC , placing always that of the vertex in the middle. The former method is used when only one angle has the same vertex; and the latter method it is necessary to use when several angles have the same vertex, to distinguish them from one another.

The measure of an angle, by which its quantity or magnitude is expressed, is an arch, as DE , described from the centre A , with any radius at pleasure, and contained between its legs AB and AC .—Hence angles are compared and distinguished by the ratio of the arcs which subtend them, to the whole circumference of the circle; or by the number of degrees contained in the arc DE by which they are measured, to 360, the number of degrees in the whole circumference of the circle. And thus an angle is said to be of so many degrees as are contained in the arc DE , by which it is measured.

Hence it matters not with what radius the arc is described, for the arcs DE , de , being similar, they have the same ratio as their respective radii or circumferences, and therefore they contain the same number of degrees.—Hence it follows, that the quantity or magnitude of the angle remains still the same, though the legs be ever so much increased or diminished.—And thus, in similar figures, the like or corresponding angles are equal.

The *taking or measuring of angles*, is an operation of great use and extent in surveying, navigation, geography, astronomy, &c. And the instruments chiefly used for this purpose, are quadrants, sextants, octants, theodolites, circumferentors, &c. Mr. Hadley invented an excellent instrument for taking the larger kind of angles, where-

much accuracy is required, or where the motion of the object, or any circumstance causing an unsteadiness in the common instruments, renders the observations difficult, or uncertain. And Mr. Dollond contrived an instrument for measuring small angles. See *Hadley's Quadrant, Micrometer, and the Philos. Trans.* Numbers 420, 425, and vol. 48.

To measure the Quantity of an Angle.

1. *On paper.* Apply the centre of a protractor to the vertex A of the angle, so that the radius may coincide with one leg, as AB ; then the degree on the arch that is cut by the other leg AC , will give the measure of the angle required.

Or thus, by a line of chords. Take off the chord of 60 with a pair of compasses; and with that radius, from the centre A , describe an arc, as DE . Then, take this arc DE between the compasses, and apply the extent to the scale of chords, which will give the degrees in the angle as before.

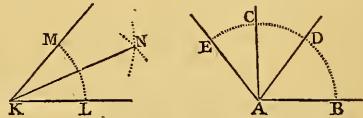

M. De Lagny gave, in several memoirs of the Royal Academy of Sciences, a new method of measuring angles, which he called Goniometry. The method consists in measuring with a pair of compasses, the arc which subtends the proposed angle; not by applying its extent to a pre-constructed scale of chords, but in the following manner: From the angular point as a centre, with a pretty large radius, describe a circle, producing one leg of the angle backwards to cut off a semicircle; then search out what part of the semicircle the arc is which measures the given angle in this manner; viz. take the extent of this arc with a very fine pair of compasses, and apply it several times to the arc of the semicircle, to find how often it is contained, with a small part remaining over; in the same manner take the extent of this small part, and apply it to the first arc, to find how often it is contained in it; and what remains this 2d time, apply in like manner to the first remainder; then the 3d remainder apply to the 2d, and so on, always counting how often the last remainder is contained in the next foregoing, till nothing remain, or till the remainder is insensible, and too small to be measured. Then, beginning at the last, and returning backwards, make a series of fractions, of which the numerators are always 1, and the denominators are the number of times each remainder is contained in its next remainder, with the fractional part more, as derived from the following remainder; then the last fraction, thus obtained, will show what part the given angle is of 180° , or the semicircle; and being turned into degrees &c., will be the measure of the angle, and nearer, it is asserted, than it can be obtained by any other means; whether it be measuring, or calculating by trigonometrical tables.—Thus, if it be required to measure the angle GHN : With a large radius describe the semicircle GHI , meeting the leg HG produced in I ; then take the extent of the arc GH in the compasses, and applying it from G upon the semicircle, suppose it contains 4 times to the point I , and the part $4I$ over; take $4I$ and apply it from H to I , so that HG contains $4I$ once, and 16 over; also apply this remainder to the former $4I$, and it is contained 5 times, from 4 to 5 , and $5I$ over; and lastly the remainder $5I$ is just twice contained in the former remainder 16 or 12 , without any remainder. Here then, the series of quotients, or numbers of times contained, are $4, 1, 5, 2$; therefore, beginning at the last, the first fraction is $\frac{1}{2}$, or the last remainder is half the preceding one; and the 2d fraction is

$\frac{1}{5\frac{1}{2}}$ or $\frac{2}{11}$; the 3d is $\frac{1}{11}$ or $\frac{1}{13}$; and the fourth is $\frac{1}{44}$ or $\frac{1}{53}$; that is, the arc GH is $\frac{1}{53}$ of a semicircle, or the angle GHN is $\frac{1}{53}$ of two right angles, or of 180° , which is equivalent to $37\frac{1}{7}$ degrees, or $37^\circ 8' 34''\frac{2}{7}$.

2. *On the ground.* Place a surveying instrument with its centre over the angular point to be measured, turning the instrument about till 0, the beginning of its arch, fall in the line or direction of one leg of the angle; then turn the index about to the direction of the other leg, and it will cut off from the arch the degrees answering to the given angle.

To plot or lay down any given angle, either on paper or on the ground, may be performed in the same manner; and the method is farther explained under the articles PLOTTING and PROTRACTING, also under the names of the several instruments.

To bisect a given angle, as suppose the angle LKM . From the centre K , with any radius, describe the arc LM ; then with the centres L and M , describe two arcs intersecting in N ; and draw the line KN , which will bisect the given angle LKM , dividing it into the two equal angles LKN , MKN .

To trisect an angle, see TRISECTION, and ANGULAR SECTIONS.

• ANGLES are of various kinds and denominations. With regard to the form of their legs, they are divided into rectilinear, curvilinear, and mixed.

Rectilinear, or right-lined ANGLE, is that whose legs are both right lines; as the foregoing angle MKL .

Curvilinear ANGLE, is that whose legs are both of them curves.

Mitred, or mixtilinear ANGLE, is that of which one leg is a right line, and the other a curve.

With regard to their magnitude, angles are again divided into right and oblique, acute and obtuse.

Right ANGLE, is that which is formed by one line perpendicular to another; or that which is subtended by a quadrant of a circle. As the angle BAC .—Therefore the measure of a right angle is a quadrant of a circle, or 90° ; and consequently all right angles are equal to each other.

Oblique ANGLE, is a common name for any angle that is not a right one; and it is either acute or obtuse.

Acute ANGLE, is that which is less than a right angle, or less than 90 degrees; as the angle BAD .

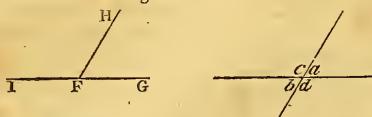

Obtuse ANGLE, is greater than a right angle, or whose measure exceeds 90 degrees; as the angle BAE .

With regard to their situation in respect of each other, angles are distinguished into contiguous, adjacent, vertical, opposite, and alternate.

Contiguous ANGLES, are such as have the same vertex, and one leg common to both. As the angles BAD , CAD , which have AD common.

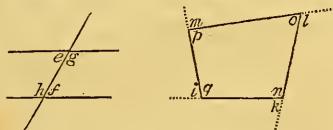

Adjacent ANGLES, are those of which a leg of the one produced forms a leg of the other: as the angles GHN and IHN , which have the legs HG and VG in a straight line.—Hence, adjacent angles are supplements to each other, making together 180 degrees. And therefore if one of

these be given, the other will be known by subtracting the given one from 180 degrees. Which property is useful in surveying, to find the quantity of an inaccessible angle; viz, measure its adjacent accessible one, and subtract this from 180 degrees.

Vertical or opposite ANGLES, are such as have their legs mutually continuations of each other; as the two angles a and b , or c and d .—The property of these is, that the vertical or opposite angles are always equal to each other, viz, $\angle a = \angle b$, and $\angle c = \angle d$. And hence the quantity of an inaccessible angle of a field, &c, may be found, by measuring its accessible opposite angle.

Alternate ANGLES, are those made on the opposite sides of a line cutting two parallel lines; so, the angles e and f , or, g and h , are alternates. And these are always equal to each other; viz, the $\angle e = \angle f$, or $\angle g = \angle h$.

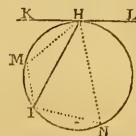

External ANGLES, are the angles of a figure made without it, by producing its sides; as the angles i , k , l , m . All the external angles of any right-lined figure, taken together, are equal to 4 right angles; and the external angle of a triangle is equal to both the internal opposite ones taken together; also any external angle of a trapezium inscribed in a circle, is equal to the internal opposite angle.

Internal ANGLES, are the angles within any figure, made by the sides of it; as the angles n , o , p , q .—In any right-lined figure, an internal angle as n , and its adjacent external angle k , together make two right angles, or 180 degrees; and all the internal angles n , o , p , q , taken together, make twice as many right angles, wanting 4, as the figure has sides; also any two opposite internal angles of a trapezium inscribed in a circle, taken together, make two right angles, or 180 degrees.

Homologous, or like ANGLES, are such angles in two figures, as retain the same order in both.

ANGLE at the centre, is that whose vertex is in the centre; as the angle AFC , formed by two radii AF , FC , and it is measured by the arc ADC .—An angle at the centre, as AFC , is always double the angle ABC at the circumference, standing on the same arc ADC ; and all angles at the centre are equal that stand upon the same or equal arcs: also all angles at the centre are proportional to the arcs they stand upon; and so also are all angles at the circumference.

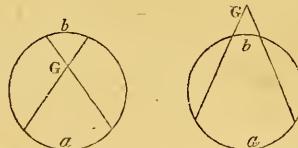

ANGLE at the circumference, is that whose vertex is somewhere in the circumference of a circle; as the angle ABC .

ANGLE in a segment, is that whose legs meet the extremities of the base of the segment, and its vertex is anywhere in its arch; as the angle n is in the segment ABC ; and is comprehended between two chords AB and BC .—An angle at the circumference is measured by half the arc ADC on which it stands; and all the angles ABC , AEC , in the same segment, are equal to each other.

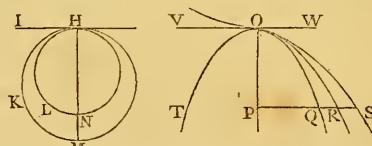

ANGLE in a semicircle is an angle at the circumference standing on a semicircle, or on a diameter.—An angle in a semicircle, is a right angle; in a greater segment, the angle is less, and in a less segment is greater, than a right angle.

ANGLE of a segment, is that made by a chord with a tangent, at the point of contact. So IHK is the angle of the less segment IMH , and IHL , the angle of the greater segment INH .—And the measure of each of these angles, is half the alternate or supplemental segment, or equal to the angle in it; viz, the $\angle IHK = \angle INH$, and the $\angle IHL = \angle IMH$.

ANGLE out of the centre, as c , is one whose vertex is not in the centre of the circle.—And its measure is half the sum $\frac{1}{2}a + \frac{1}{2}b$ of the arcs intercepted by its legs when it is within the circle, or half the difference $\frac{1}{2}a - \frac{1}{2}b$ when it is without.

ANGLE of a semicircle, is the angle which the diameter of a circle makes with the circumference. Euclid demonstrates that this is less than a right angle, but greater than any acute angle.

ANGLE of contact, is that made by a curve line and a tangent to it, at the point of contact; as the angle IHK . It is proved by Euclid, that the angle of contact between a right line and a circle, is less than any right-lined angle whatever; though it does not therefore follow that it is of no magnitude or quantity. This has been the subject of great disputes among geometers, in which Peletarius, Clavius, Taquet, Wallis, &c, bore a considerable share; Peletarius and Wallis contending that it is no angle at all, against Clavius, who rightly asserts that it is not absolutely nothing in itself, but only of no magnitude in comparison with a right-lined angle, being a quantity of a different kind or nature; like as a line in respect to a surface, or a surface in respect to a solid, &c. And since his time, it has been proved by sir Isaac Newton, and others, that angles of contact can be compared to each other, though not to right-lined angles, and what

the proportions are which they bear to each other. Thus, the circular angles of contact, IHK , IHL , are to each other in the reciprocal subduplicate ratio of the diameters HH' , $\text{H}'\text{H}$. And hence the circular angle of contact may be divided, by describing intermediate circles, into any number of parts, and in any proportion. And if, instead of circles, the curves be parabolas, and the point of contact H or o the common vertex of their axes; the angles of contact will then be reciprocally in the subduplicate ratio of their parameters. But in such elliptical and hyperbolical angles of contact, these will be reciprocally in the subduplicate of the ratio compounded of the ratios of the parameters, and the transverse axes. Moreover, if TOQ be a common parabola, to the axis OP , and tangent VOW , and whose equation is $1 \times x = y^2$, or $x = y^2$, where x is the absciss OP , and y the ordinate PQ , the parameter being 1; and if OP , OS , &c, be other parabolas to the same axis, tangent, and parameter, their ordinate y being PR , PS , &c, and their equations $x = y^3$, $x = y^4$, $x = y^5$, &c: then the series of angles of contact will be in succession infinitely greater than each other, viz, the angle of contact WOP infinitely greater than WOS , and this infinitely greater than WOS , and so in infinitum.

And farther, between the angles of contact of any two of this kind, may other angles of contact be found *ad infinitum*, which shall infinitely exceed each other, and yet the greatest of them be infinitely less than the smallest right-lined angle. So also $x^2 = y^3$, $x^3 = y^4$, $x^4 = y^5$, &c, denote a series of curves, of which every succeeding one makes an angle with its tangent, infinitely greater than the preceding one; and the least of these, viz, that whose equation is $x^2 = y^3$, or the semicubical parabola, is infinitely greater than any circular angle of contact.

ANGLES are again divided into *plane*, *spherical*, and *solid*.

Plane ANGLES, are all those above treated of; which are defined by the inclination of two lines in a plane, meeting in a point.

Spherical ANGLE, is an angle formed on the surface of a sphere by the intersection of two great circles; or, it is the inclination of the planes of those circles.

The measure of a spherical angle, is the arc of a great circle of the sphere, intercepted between the two planes which form the angle, and which cuts the said planes at right angles. For their properties, &c, see SPHERE, SPHERICAL, and SPHERICAL TRIGONOMETRY.

Solid ANGLE, is the mutual inclination of more than two planes, or plane angles, meeting in a point, and not contained in the same plane; like the angles or corners of solid bodies. For their measure, properties, &c, see SOLID Angle.

Angles of other less usual kinds and denominations, are also to be found in some books of Geometry. As,

Horned ANGLE, *angulus cornutus*, that which is made by a right line, whether a tangent or secant, with the circumference of a circle.

Lunular ANGLE, *angulus lunularis*, is that which is formed by the intersection of two curve lines, the one concave, and the other convex.

Cissoid ANGLE, *angulus cissoides*, the inner angle made by two spherical convex lines intersecting each other.

Sistroid ANGLE, *angulus sistroides*, is that which is in the form of a sistrum.

Pelccoid ANGLE, *angulus pelcooides*, is that in the form of a hatchet.

ANGLE, in Trigonometry. See TRIANGLE, TRIGONOMETRY, SINE, TANGENT, &c.

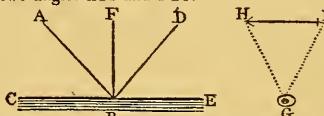

ANGLE, in Mechanics.—*Angle of Direction*, is that which is comprehended between the lines of direction of two conspiring forces.

ANGLE of Elevation, is that which is comprehended between the line of direction and any plane on which the projection is made, whether horizontal or oblique.

ANGLE of Incidence, is that made by the line of direction of an impinging body, at the point of impact. As the angle ABC .

ANGLE of Reflection, is that made by the line of direction of the reflected body, at the point of impact. As the angle DBE .

Instead of the angles of incidence and reflection being estimated from the plane on which the body impinges, sometimes the complements of these are understood, viz, as estimated from a perpendicular to the reflecting plane; as the two angles ABF and DBF .

ANGLE, in Optics.—*Visual or Optic Angle*, is the angle included between the two rays drawn from the two extreme points of an object to the centre of the pupil of the eye: as the angle HEI . The apparent magnitude of objects, when their distance cannot be compared, is greater or less, according to the angle under which they appear.—Objects seen under the same or an equal angle, appear equal.—But there is an exception to this rule in the case of the heavenly bodies, which are really seen under a less angle in the horizon than when they have attained any sensible degree of elevation (see REFRACTION); notwithstanding which, it must have been observed by every one that they appear larger in the horizon, than in any other part of their course; this becomes still more sensible if we observe the distance of two stars at their rising, and again when they are near the zenith, their apparent distance in the former case being considerably greater than in the latter, yet if their angular distance be measured by a sextant, it will be found to increase as their distance from the zenith decreases. (See APPARENT MAGNITUDE.)

The least visible angle, or least angle under which a body can be seen, according to Dr. Hooke, is one minute; but Dr. Jurin shows, that at the time of his debate with Hevelius on this subject, the latter could probably discover a single star under so small an angle as $20''$. But bodies are visible under smaller angles as they are more bright or luminous. Dr. Jurin states the grounds of this controversy, and discusses the question at large, in his Essay on distinct and indistinct Vision, published in Smith's Optics, pa. 148, *et seqq.*

ANGLE of the interval, of two places, is the angle subtended by two lines directed from the eye to those places.

ANGLE of incidence, or *reflection*, or *refraction*, &c. See the respective words INCIDENCE, REFLECTION, REFRACTION, &c.

ANGLE, in Astronomy.—*Angle of Commutation*. See COMMUTATION.

ANGLE of elongation, or *Angle at the Earth*. See ELONGATION.

Parallactic ANGLE, or the *parallax*, is the angle made at the centre of a star, or the sun, &c, by two lines drawn, the one to the centre of the earth, and the other to its surface. See PARALLACTIC, and PARALLAX.

ANGLE of the position of the sun, of the sun's apparent semi-diameter, &c. See the respective words.

ANGLE at the sun, is the angle under which the distance of a planet from the ecliptic is seen from the sun.

ANGLE of the East. See NONAGESIMAL.

ANGLE of obliquity, of the ecliptic, or the angle of inclination of the axis of the earth to the axis of the ecliptic, is now nearly $23^{\circ} 28'$. See OBLIQUITY, and ECLIPIC.

ANGLE of longitude, is the angle which the circle of a star's longitude makes with the meridian, at the pole of the ecliptic.

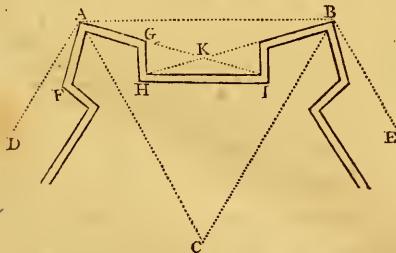

ANGLE of right ascension, is the angle which the circle of a star's right ascension makes with the meridian at the pole of the equator.

ANGLE, in Navigation. **ANGLE of the rhumb, or loxodromic angle.** See RHUMB and LOXODROMIC.

ANGLES, in Fortification, are understood of those formed by the several lines used in fortifying, or making a place defensible.

These are of two sorts; *real* and *imaginary*.—Real angles are those which actually exist and appear in the works. Such as the flanked angle, the angle of the epaule, angle of the flank, and the re-entering angle of the counterscarp. Imaginary, or occult angles, are those which are only subservient to the construction, and which exist no more after the fortification is drawn. Such as the angle of the centre, angle of the polygon, flanking angle, salient angle of the counterscarp, &c.

ANGLE of, or at, the centre, is the angle formed at the centre of the polygon, by two radii drawn from the centre to two adjacent angles, and subtended by a side of it, as the angle $\angle ACB$. This is found by dividing 360 degrees by the number of sides in the regular polygon.

ANGLE of the Polygon, is the angle intercepted between two sides of the polygon; as $\angle DAB$, or $\angle ABE$. This is the supplement of the angle at the centre, and is therefore found by subtracting the angle c from 180 degrees.

ANGLE of the Triangle, is half the angle of the polygon; as $\angle CAB$ or $\angle CBA$; and is therefore half the supplement of the angle c at the centre.

ANGLE of the Bastion, is the angle $\angle FAG$, made by the two faces of the bastion. And is otherwise called the flanked angle.

Diminished ANGLE, is the angle $\angle BAG$, made by the meeting of the exterior side of the polygon with the face AG of the bastion.

VOL. I.

ANGLE of the curtain, or of the *flank*, is the angle $\angle GHG$, made between the curtain and the flank.

ANGLE of the epaule, or *shoulder*, is the angle $\angle AGH$, made by the flank and the face of the bastion.

ANGLE of the tenaille, or exterior flanking angle, is the angle $\angle AKB$, made by the two rasant lines of defence, or the faces of two bastions produced.

ANGLE of the counterscarp, is the angle made by the two sides of the counterscarp, meeting before the middle of the curtain.

ANGLE flanking inward, is the angle made by the flanking line with the curtain.

ANGLE forming the flank, is that consisting of one flank and one demigore.

ANGLE forming the face, is that composed of one flank and one face.

ANGLE of the moat, is that made before the curtain, where it is intersected.

Re-entering, or re-entrant ANGLE, is that whose vertex is turned inwards, towards the place; as H or I .

Salient, or sortant ANGLE, is that turned outwards, advancing its point towards the field; as A or G .

Dead ANGLE, is a re-entering angle, which is not flanked or defended.

ANGLE of a wall, in Architecture, is the point or corner where the two sides or faces of a wall meet.

ANGUINEAL Hyperbola, a name given by Sir Isaac Newton to four of his curves of the second order, viz, species 33, 34, 35, 36, expressed by the equation $xy^2 + ey = -ax^3 + bx^2 + ex + d$; being hyperbolae of a serpentine figure. See CURVES.

ANGULAR, something relating to, or that hath angles.

At a distance, angular bodies appear round; the angles and small inequalities disappearing at a much less distance than the bulk of the body.

ANGULAR Motion, is the motion of a body which moves circularly about a point; or the variation in the angle described by a line, or radius, connecting a body with the centre about which it moves.—Thus, a pendulum has an angular motion about its centre of motion; and the planets have an angular motion about the sun.—Two moveable points M and O , of which the one describes the arc MN , and the other the arc OP , in the same time, have an equal, or the same angular motion, though the real motion of the point O be much greater than that of the point M , viz, as the arc OP is greater than the arc MN . The angular motions of revolving bodies, as of the planets about the sun, are reciprocally proportional to their periodic times. And they are also, as their real or absolute motions directly, and as their radii of motion inversely.

ANGULAR motion is also a kind of compound motion composed of a circular and a rectilinear motion; like the wheel of a coach, or other vehicle.

ANGULAR SECTIONS, the dividing of angles into some number of equal parts; as, to bisect, or to trisect an angle, &c.

Euclid taught how to bisect an angle, viz, in prop. 9, book 1; but his geometry goes not farther. The other ancients after him endeavoured to trisect an angle; in which attempt, as Euclid's geometry failed them, they had recourse to the conic sections, which had been ad-

R

mitted into geometry, by means of which, and a problem in Apollonius's Inclinations, they effected the trisection; which was equivalent to solving a cubic equation. Pappus, in the 34th, and following props. of book 4, treats of the trisection; and in the 36th et seq. of any section in general. Many of the moderns have also treated of angular sections; as, Vieta, Alex. Anderson, Wallis, Briggs, l'Hopital, Guisne, Emerson, &c. See SECTION and TRISECTION, &c.

ANNUAL, in Astronomy, something that returns every year, or which terminates with the year.

ANNUAL motion of the earth. See EARTH.

ANNUAL argument of longitude. See ARGUMENT.

ANNUAL epacts. See EPACT.

ANNUAL equation of the mean motion of the sun and moon, and of the moon's apogee and nodes. See EQUATION.

ANNUITIES, any periodical incomes, arising from money lent, or from houses, lands, salaries, pensions, &c.; payable from time to time; either annually, or at other intervals of time.

Annuities may be divided into such as are certain, and such as depend on some contingency, as the continuance of a life, &c. See LIFE ANNUITIES.

Annuities are also divided into annuities in possession, and annuities in reversion; the former meaning such as have commenced; and the latter such as will not commence till some particular event has happened, or till some given period of time has elapsed.

Annuities may be farther considered as payable either yearly, or half yearly, or quarterly, &c.

The present value of an annuity, is that sum, which, being improved at interest, will be sufficient to pay the annuity.

The present value of annuity certain, payable yearly, is calculated in the following manner.—Let the annuity be 1*l.* and let *r* denote the amount of 1*l.* for a year, or 1*l.* increased by its interest for one year. Then, 1 being the present value of the sum *r*, and having to find the present value of the sum 1*l.* it will be, by proportion thus, $r : 1 :: 1 : \frac{1}{r}$ the present value of 1*l.* due a year hence. And for

the same reason $\frac{a}{r}$ is the present value of *a* pounds due a year hence; the present value being always in direct proportion to the yearly payment. So that, in what follows, we shall only consider the annuity as 1*l.*; and whatever results are thus obtained, being multiplied by *a*, will correspond to an annuity of *a* pounds.

Now since $\frac{1}{r}$ is the present value of 1*l.* due a year hence, so likewise $\frac{1}{r^2}$ will be the present value of 1*l.* due 2 years hence; for $r : 1 :: \frac{1}{r} : \frac{1}{r^2}$. So also $\frac{1}{r^3}, \frac{1}{r^4}, \frac{1}{r^5}, \&c.$, will be the present value of 1*l.* due at the end of 3, 4, 5, &c. years, respectively; and in general, $\frac{1}{r^n}$ will be the value of 1*l.* to be received after the expiration of *n* years. Consequently the sum of all these, or $\frac{1}{r} + \frac{1}{r^2} + \frac{1}{r^3} + \frac{1}{r^4} + \&c.$, continued to *n* terms, will be the present value of all the *n* years annuities. And the value of the perpetuity, is the sum of the series continued to infinity.

But this series, it is evident, is a geometrical progres-

sion, the first term and common ratio being each $\frac{1}{r}$, and the number of its terms *n*; therefore the sum *s* of all the terms, or the present value of all the annual payments, will be $s = \frac{1}{r-1} - \frac{1}{r-1} \times \frac{1}{r^n}$.

When the annuity is a perpetuity, it is plain that the last quantity $\frac{1}{r^n}$ vanishes, and therefore $\frac{1}{r-1} \times \frac{1}{r^n}$ also vanishes; consequently the expression becomes barely $s = \frac{1}{r-1}$; that is, $\frac{1}{r-1}$ is the present value of the perpetuity of an annuity of 1*l.* per ann. and consequently $\frac{a}{r-1}$ will be the present value of the perpetuity of *a* pounds per ann.; hence any annuity divided by the interest of 1*l.* for one year, is the value of the perpetuity. So, if the rate of interest be 5 per cent. and yearly payments, then $\frac{100}{5} a = 20a$ is the value of the perpetuity. Also $\frac{100}{4} a = 25a$ is the value of the perpetuity at 4 per cent. And $\frac{100}{3} a = 33\frac{1}{3} a$ is the value of the perpetuity at 3 per cent. interest. And so on.

If the annuity is not to be entered on immediately, but after a certain time, as *m* years; then the present value of the reversion is equal to the difference between two present values, the one of the first term of *m* years, and the other for the end of the last term *n*: that is, equal to the difference between $\frac{1}{r-1} - \frac{1}{r-1} \times \frac{1}{r^m}$ and $\frac{1}{r-1} - \frac{1}{r-1} \times \frac{1}{r^n}$, or $= \frac{1}{r-1} \times (\frac{1}{r^m} - \frac{1}{r^n})$.

Annuities certain differ in value, as they are made payable yearly, half-yearly, or quarterly. And by proceeding as above, using the interest or amount of a half year, or a quarter, as those for the whole year were used, the following set of theorems will arise; where *r* denotes, as before, the amount of 1*l.* and its interest for a year, and *n* the number of years, during which, any annuity is to be paid; also *p* denotes the perpetuity $\frac{1}{r-1}$, *x* denotes $\frac{1}{r-1} - \frac{1}{r-1} \times \frac{1}{r^n}$ the present value of the annuity supposed payable yearly, *y* the present value of the same when it is payable half-yearly, and *q* the same when payable quarterly; or universally, *m* the present value when it is payable every *m* part of a year.

$$\text{THEOR. 1. } Y = P - P \times \left(\frac{1}{r}\right)^n.$$

$$\text{THEOR. 2. } Y = P - P \times \left(\frac{2}{r+1}\right)^{2n}.$$

$$\text{THEOR. 3. } Q = P - P \times \left(\frac{4}{r+3}\right)^{4n}.$$

$$\text{THEOR. 4. } M = P - P \times \left(\frac{m}{r+m-1}\right)^{mn}.$$

Exam. 1.—Let the rate of interest be 4 per cent., and the term 5 years; and consequently $r = 1.04$, $n = 5$, $P = 25a$; also let $m = 12$, or the interest payable monthly in theorem 4: then the present value of an annuity of *a* pounds a year, for 5 years, according as it is supposed payable yearly, or every half year, or every quarter, or every month or $\frac{1}{12}$ th part of a year, will be as follows:

$$Y = 25 - 25 \times .821928 = 4.4518$$

$$Y = 25 - 25 \times .820348 = 4.4913$$

$$Q = 25 - 25 \times .819543 = 4.5114$$

$$M = 25 - 25 \times .818996 = 4.5251$$

Exam. 2. Supposing the annuity to continue 25

years, the rate of interest and every thing else being as before; then the values of the annuities for 25 years will be

$$\begin{aligned} Y &= 25 - 25 \times .375118 = 15.6221 \\ H &= 25 - 25 \times .371527 = 15.7118 \\ Q &= 25 - 25 \times .369709 = 15.7573 \\ M &= 25 - 25 \times .368477 = 15.7881 \end{aligned}$$

Exam. 3. And if the term be 50 years, the values will be

$$\begin{aligned} Y &= 25 - 25 \times .140713 = 21.4822 \\ H &= 25 - 25 \times .138032 = 21.5492 \\ Q &= 25 - 25 \times .136685 = 21.5829 \\ M &= 25 - 25 \times .135775 = 21.6056 \end{aligned}$$

Exam. 4. Also if the term be 100 years, the values will be

$$\begin{aligned} Y &= 25 - 25 \times .019800 = 24.5050 \\ H &= 25 - 25 \times .019053 = 24.5237 \\ Q &= 25 - 25 \times .018683 = 24.5329 \\ M &= 25 - 25 \times .018435 = 24.5391 \end{aligned}$$

Hence the difference in the value by making periods of payments smaller, for any given term of years, is the more as the intervals are smaller, or the periods more frequent. The same difference is also variable, both as the rate of interest varies, and also as the whole term of years n varies; and, for any given rate of interest, it is evident that the difference, for any periods m of payments, first increases from nothing as the term n increases, from 0, to some certain finite term or value of n , when the difference D is the greatest or a maximum; and that afterwards, as n increases more, that difference will continually decrease to nothing again, and vanish when n is infinite: also the term or value of n , for the maximum of the difference, will be different according to the periods of payment, or value of m .

Annuities may also be considered as in arrears, or as forborn, for any number of years; in which case each payment is to be considered as a sum put out to interest for the remainder of the term after the time it becomes due. And as 1*l.* due at the end of 1 year, amounts to r at the end of another year, and to r^2 at the end of the 3d year, and to r^3 at the end of the 4th year, and so on; therefore, by adding always the last year's annuity, or 1, to the amounts of all the former years, the sum of all the annuities and their interests, will be the sum of the following geometrical series, $1 + r + r^2 + r^3 + r^4 + \dots$ to r^{n-1} , continued till the last term be r^{n-1} , or till the number of terms be n , the number of years the annuity is forborn. But the sum of this geometrical progression is $\frac{r^n - 1}{r - 1}$, which therefore is the amount of 1*l.* annuity forborn for n years. And this quantity being multiplied by a instead of 1, will produce the amount for the annuity a .

But the amounts of annuities, or their present values, are easiest found by the two following tables of numbers for the annuity of 1*l.* ready computed from the foregoing principles.

TABLE I.—Continued.
The Amount of an Annuity of 1*l.* at Comp. Interest.

Yrs.	at 3 per cent.	3½ per cent.	4 per cent.	4½ per cent.	5 per cent.	6 per cent.
1	1.00000	1.00000	1.00000	1.00000	1.00000	1.00000

THE USE OF TABLE I.

To find the Amount of an annuity forborn any number of years. Take out the amount from the 1st table, for the proposed years and rate of interest; then multiply it by the annuity in question; and the product will be its amount, for the same number of years, and rate of interest.—And the converse, to find the rate or time.

Exam. 1. To find how much an annuity of 50*l.* will amount to in 20 years at 3½ per cent. compound interest.—On the line of 20 years, and in the column of 3½ per cent, stands 28.27968, which is the amount of an annuity of 1*l.* for the 20 years; and therefore 28.27968 multiplied by 50, gives 1413.984*l.* or 1413*l.* 19s. 8d. for the answer.

Exam. 2. In what time will an annuity of 20*l.* amount to 1000*l.* at 4 per cent. compound interest?—Here the amount of 1000*l.* divided by 20*l.* the annuity, gives 50, the amount of 1*l.* annuity for the same time and rate.

Then, the nearest tabular number in the column of 4 per cent. is 49.96758, which standing on the line of 28, shows that 28 years is the answer.

Exam. 3. If it be required to find at what rate of interest an annuity of 20*l.* will amount to 1000*l.* forborn for 28 years.—Here 1000 divided by 20 gives 50 as before. Then looking along the line of 28 years, for the nearest to this number 50, we find 49.96758 in the column of 4 per cent. which is therefore the rate of interest required.

TABLE II.
The present Value of an Annuity of 1*l.*

THE USE OF TABLE II.

Exam. 1. To find the present value of an annuity of 50*l.* which is to continue 20 years, at $3\frac{1}{2}$ per cent.—By the table, the present value of 1*l.* for the same rate and time,

is 14.21240; therefore $14.2124 \times 50 = 710.62l.$ or 710*l.* 12*s.* 4*d.* is the present value sought.

Exam. 2. To find the present value of an annuity of 20*l.* to commence 10 years hence, and then to continue for 40 years, or to terminate 50 years hence, at 4 per cent. interest.—In such cases as this, it is plain we have to find the difference between the present values of two equal annuities, for the two given times; which therefore will be effected by subtracting the tabular value of the one term from that of the other, and multiplying by the annuity. Thus,

tabular value for 50 years	21.48218
tabular value for 10 years	8.11090
the difference	13.37128
mult. by -	20
gives -	267.4256
or -	267.18s.6d. the answer.

The foregoing observations, rules, and tables, contain all that is important in the doctrine of annuities certain. And for further information, reference may be had to arithmetical writings, particularly Malcolm's Arithmetic, page 595; Simpson's Algebra, sect. 16; Dodson's Mathematical Repository, page 298, &c; Jones's Synopsis, ch. 10; Philos. Trans. vol. lxvi, page 109.

For what relates to the doctrine of annuities on lives, see ASSURANCE, COMPLEMENT, EXPECTATION, LIFE ANNUITIES, REVERSIONS, &c

ANNULETS, in Architecture, are small square members, in the Doric capital, placed under the quarter round.

Annulet is also used for a narrow flat moulding, common to other parts of a column, as well as to the capital; and so called, because it encompasses the column around. In which sense annulet is frequently used for baguette, or little astragal.

ANNULUS, a species of VOLUTA. See also RING.

ANOMALISTICAL Year, in Astronomy, called also *periodical year*, is the space of time in which the earth, or a planet, passes through its orbit. The anomalistical, or common year, is somewhat longer than the tropical year; by reason of the precession of the equinox.

And the apses of all the planets have a like progressive motion; by which it happens, that a longer time is necessary to arrive at the aphelion, which has advanced a little, than to arrive at the same fixed star. For example, the tropical revolution of the sun, with respect to the equinox, is

365^a 6^b 48^m 45^s;

but the sidereal, or return to the same star, - - - - - 365 6 9 10 $\frac{1}{2}$ and the anomalistic revolution is 365 6 15 20, because the sun's apogee advances each year 65 $\frac{1}{2}$ with respect to the equinoxes, and the sun cannot arrive at the apogee till he has passed over the 65 $\frac{1}{2}$ more than the revolution of the year answering to the equinoxes.

To find the anomalistic revolution, say, As the whole secular motion of a planet minus the motion of its aphelion, is to 100 years or 3155760000 seconds, so is 360⁰, to the duration of the anomalistic revolution.

ANOMALOUS, is something irregular, or that deviates from the ordinary rule and method of other things of the same kind.

ANOMALY, in Astronomy, is an irregularity in the motion of a planet, by which it deviates from the aphelion or apogee; or it is the angular distance of the planet from

the aphelion or apogee; that is, the angle formed by the line of the apses, and another line drawn through the planet.

Kepler distinguishes three kinds of anomaly; mean, eccentric, and true.

Mean or Simple ANOMALY, in the ancient astronomy, is the distance of a planet's mean place from the apogee. Which Ptolemy calls the angle of the mean motion.

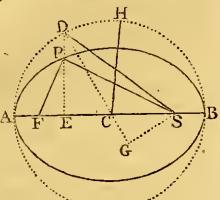

But in the modern astronomy, in which a planet P is considered as describing an ellipse APB about the sun S , placed in one focus, it is the time in which the planet moves from its aphelion A , to the mean place or point of its orbit.

Hence, as the elliptic area ASD is proportional to the time in which the planet describes the arc AP , that area may represent the mean anomaly.—Or, if PD be drawn perpendicular to the transverse axis AB , and meet the circle in D described on the same axis; then the mean anomaly may also be represented by the circular trilineal ASD , which is always proportional to the elliptic one ASP , as is proved in my Mensuration, pr. 8, page 223, 4th edition.—Or, drawing SG perpendicular to the radius DC produced; then the mean anomaly is also proportional to $SG +$ the circular arc AD , as is demonstrated by Keil in his Lect. Astron.—Hence, taking $DH = SG$, the arc AH , or angle ACD will be the mean anomaly in practice, as expressed in degrees of circle, the number of those degrees being to 360° , as the elliptic trilineal area ASP , is to the whole area of the ellipse; the degrees of mean anomaly, being those in the arc AH , or angle ACD .

Eccentric ANOMALY, or of the centre, in the modern astronomy, is the arc AD of the circle ADA intercepted between the aphelion A , and the point D , determined by the perpendicular DPE to the line of the apses, drawn through the place P of the planet. Or it is the angle ACD at the centre of the circle.—Hence the eccentric anomaly is to the mean anomaly, as AD to $AD + SG$, or as AD to AH , or as the angle ACD to the angle ACH .

True or Equated ANOMALY, is the angle ASP at the sun, which the planet's distance AP from the aphelion, appears under; or the angle formed by the radius vector, or line SP , drawn from the sun to the planet, with the line of the apses.

The true anomaly being given, it is easy from it to find the mean anomaly. For the angle ASP , which is the true anomaly, being given, the point P in the ellipse is given, and thence the proportion of the area ASP to the whole ellipse, or of the mean anomaly to 360 degrees. And for this purpose, the following easy rules for practice are deduced from the properties of the ellipse, by M. de la Caille, in his Elements of Astronomy, and M. de la Lande, art. 1240 &c of his Astronomy: 1st, as the square root of SB the perihelion distance, is to the square root of SA the aphelion distance, so is the tangent of half the true anomaly ASP , to the tangent of half the eccentric anomaly ACD . 2d, The difference DH or SG between the eccentric and mean anomaly, is equal to the product of the eccentricity cs , by the sine of SG the eccentric anomaly just found. And in this case, it is proper to express the eccentricity in seconds of a degree, which will be

found by this proportion, as the mean distance l : the eccentricity $: : 206264.8$ seconds, or $57^{\circ} 17' 44'' s$, in the arch whose length is equal to the radius, to the seconds in the arc which is equal to the eccentricity cs ; which being multiplied by the sine of the eccentric anomaly, to radius l , as above, gives the seconds in SG , or in the arc DH , being the difference between the mean and eccentric anomalies. 3d, To find the radius vector SP , or distance of the planet from the sun, say either, as the sine of the true anomaly is to the sine of the eccentric anomaly, so is half the less axis of the orbit, to the radius vector SP ; or as the sine of half the true anomaly is to the sine of half the eccentric anomaly, so is the square root of the perihelion distance SB , to the square root of the radius vector, or planet's distance SP .

But the mean anomaly being given, it is not so easy to find the true anomaly, at least by a direct process. Kepler, who first proposed this problem, could not find a direct way of resolving it, and therefore made use of an indirect one, by the rule of false position, as may be seen page 695 of Kepler's Epitom. Astron. Copernic. See also § 628 Wolfius Elem. Astron. Now the easiest method of performing this operation, would be to work first for the eccentric anomaly, viz, assume it nearly, and from it, so assumed, compute what would be its mean anomaly by the rule above given, and find the difference between this result and the mean anomaly given; then assume another eccentric anomaly, and proceed in the same way with it, finding another computed mean anomaly, and its difference from the given one; and treating these differences as in the rule of position for a nearer value of the eccentric anomaly: repeating the operation till the result comes out exact. Then, from the eccentric anomaly, thus found, compute the true anomaly by the 1st rule above laid down.

Of this problem, Dr. Wallis first gave the geometrical solution by means of the protracted cycloid; and Sir Isaac Newton did the same at prop. 31, lib. 1 Princip. But these methods being unfit for the purpose of the practical astronomer, various series for approximation have been given, viz, several by Sir Isaac Newton in his Fragmenta Epistolarum, page 26, as also in the Schol. to the prop. above-mentioned, which is his best, being not only proper for the planets, but also for the comets, whose orbits are very eccentric. Dr. Gregory, in his Astron. lib. 3, has also given the solution by a series, as well as M. Reyneau, in his Analyse Demontrée, p. 713, &c. And a better still for converging is given by Keil in his Praelect. Astron. p. 375: he says, if the arc AH be the mean anomaly, calling its sine e , cosine f , the eccentricity g , also putting $z = ge$, and $a = 1 + fg$; then the eccentric anomaly AD will be $= \frac{rz}{a} \times (1 - \frac{z^2}{a^2} &c)$, supposing $r = 57.29578$ degrees; of which the first term $\frac{rz}{a}$ is sufficient for all the planets, even for Mars itself, where the error will not exceed the 200th part of a degree; and in the orbit of the earth, the error is less than the 10000th part of a degree.

Dr. Seth Ward, in his Astronomia Geometrica, takes the angle APP' at the other focus, where the sun is not, for the mean anomaly, and thence gives an elegant solution. But this method is not sufficiently accurate when the orbit is very eccentric, as in that of the planet Mars, as is shown by Bullialdus, in his defence of the Philolaic. Astron, against Dr. Ward. However, when Newton's cor-

rection is made, as in the schol. above-mentioned, and the problem resolved according to Ward's hypothesis, Sir Isaac affirms that, even in the orbit of Mars, there will scarce ever be an error of more than one second.

ANSÆ, ANSES, in Astronomy, those seemingly prominent parts of the ring of the planet Saturn, perceived in its opening, and appearing like handles to the body of the planet; from which appearance the name ansæ is taken.

ANSER, in Astronomy, a small star, of the 5th or 6th magnitude, in the milky-way, between the eagle and swan, first brought into order by Hevelius.

ANTARCTIC pole, denotes the southern pole, or southern end of the earth's axis.—The stars near the antarctic pole never appear above our horizon in these northern latitudes.

ANTARCTIC circle, is a small circle parallel to the equator, at the distance of $23^{\circ} 28'$ from the antarctic or south pole.—At one time of the year the sun never rises above the horizon of any part within this circle; and at other times he never sets.

ANTARES, in Astronomy, the scorpion's heart; a fixed star of the first magnitude, in the constellation Scorpio.

ANTECANIS, is used by some astronomers, to denote the constellation otherwise called Canis Minor, or the star Procyon. It is so called, as preceding, or being the forerunner of, the Canis Major, and rising a little before it.

ANTECEDENT, of a ratio, denotes the first of the two terms of the ratio, or that term which is compared with the other. Thus, if the ratio be 2 to 3 , or a to b ; then 2 or a is the antecedent.

ANTECEDENTAL Method, is a branch of general geometrical proportion, or universal comparison, and is derived from an examination of the Antecedents of ratios, having given consequents, and a given standard of comparison, in the various degrees of augmentation and diminution, which they undergo by composition and decomposition. This is a method invented by Mr. James Glenie, and published by him in 1793; a method which he says he always used instead of the fluxional and differential methods, and which is totally unconnected with the ideas of motion and time. See the author's treatise above-mentioned, and also his Doctrine of Universal Comparison, or General Proportion, 1789, upon which it is founded.

ANTECEDENTIA, a term used by astronomers when a planet &c moves westward, or contrary to the order of the signs aries, taurus, &c. When it moves eastward, or according to the order of the signs aries, taurus, &c, it is then said to move in consequentia.

ANTECIANS, or ANTOECI, in Geography, the inhabitants of the earth which occupy the same semicircle of the same meridian, but equally distant from the equator, the one north and the other south; as Peloponnesus and the Cape of Good Hope.

These have their noon, or midnight, or any other hour at the same time; but their seasons are contrary, being spring to the one, when it is autumn with the other; and summer with the one, when it is winter with the other; also the length of the day to the one, is equal to the length of night to the other.

ANTES, in Architecture, are small pilasters placed at the corners of buildings.

ANTICS, in Architecture, figures of men, beasts, &c, placed as ornaments to buildings.

ANTICUM, in Architecture, a porch before a door; also that part of a temple, which is called the outer temple, and lies between the body of the temple and the portico.

ANTILOGARITHM, the complement of the logarithm of a sine, tangent, secant, &c, to that of the radius. This is found by beginning at the left hand, and subtracting each figure from 9, but the last figure from 10.

ANTINOUS, in Astronomy, a part of the constellation aquila, or the eagle.

ANTIOCHIAN Sect, or Academy, a name given to the fifth academy or branch of academics. It took its name from being founded by Antiochus, a philosopher contemporary with Cicero; and it succeeded the Philonian academy. Though Antiochus was really a stoic, and only nominally an academic.

ANTIOCHIAN epocha, a method of computing time from the proclamation of liberty granted to the city of Antioch, about the time of the battle of Pharsalia.

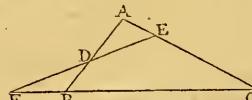

ANTIPARALLELs, in Geometry, are those lines which make equal angles with two other lines, but contrary ways; that is, calling the former pair the 1st and 2d lines, and the latter pair the 3d and 4th lines, if the angle made by the 1st and 3d lines be equal to the angle made by the 2d and 4th, and contrariwise the angle made by the 1st and 4th equal to the angle made by the 2d and 3d; then each pair of lines are antiparallel with respect to the other, viz, the 1st and 2d, and the 3d and 4th. Thus, if αA and αC be any two lines, and βE and βF be two others, cutting them so,

that the angle B is equal to the angle E ,

and the angle C is equal to the angle F ; then βC and βE are antiparallel with respect to αA and αC ; also these latter are antiparallel with regard to the two former.—See also SUBCONTRARY.

It is a property of these lines, that each pair cuts the other into proportional segments, taking them alternately,

viz, $A B : A C :: A E : A D :: D E : B C$,
and $F E : F C :: F B : F D :: D B : E C$.

ANTIPODES, in Geography, are the inhabitants of two places on the earth which lie diametrically opposite to each other, or that walk feet to feet; that is, if a line be continued down from our feet, quite through the centre of the earth, till it arrive at the surface on the other side, it will fall on the feet of our Antipodes, and vice versa.—Antipodes are 180 degrees distant from each other every way, on the surface of the globe; they have equal latitudes, the one north and the other south, but they differ by 180 degrees of longitude: they have therefore the same climates or degrees of heat and cold, with the same seasons and length of days and nights; but all of these at contrary times, it being day to the one, when it is night to the other, summer to the one when it is winter to the other, &c.: they have also the same horizon, the one being as far distant on the one side, as the other on the opposite, and therefore when the sun, &c, rises to the one, it sets to the other. The Antipodes to London are a part a little south of New Zealand.

It has been said that Plato first started the notion of

Antipodes, and gave them the name; which is likely enough, as he conceived that the earth was of a globular figure. But there have been many disputes on this point, the fathers of the church having greatly opposed it, especially Lactantius and Augustine, who pretended to laugh at it, and were greatly perplexed to think how men and trees should hang pendulous in the air with their feet up-
permost, as they thought must be the case in the other hemisphere.

ANTISCANS, or ANTISCIÆ, in Geography, are people who dwell in the opposite hemispheres of the earth, as to north and south, and whose shadows at noon fall in contrary directions. This term is more general than anteciæ, with which it is often confounded. The Antiscians stand contradistinguished from Periscians.

ANTECIÆ, see **ANTISCANS.**

APERTURE, in Optics, is the hole next the object-glass of a telescope or microscope, through which the light and the image of the object come into the tube, and are then conveyed to the eye. Aperture is also understood of that part of the object-glass itself which covers the former, and which is left pervious to the rays.

A great deal depends on having a just aperture.—To find it experimentally: apply several circles of dark paper, of various sizes, on the face of the glass, from the breadth of a straw, to such as leave only a small hole in the glass; and with each of these, separately, view some distinct objects, as the moon, stars, &c; then that aperture is to be chosen through which they appear the most distinctly.

Huygens first found the use of apertures to conduce much to the perfection of telescopes; and he found by experience (*Dioptr. prop. 56*) that the best aperture for an object-glass, for example of 30 feet, is to be determined by this proportion, as 30 to 3, so is the square root of 30 times the distance of the focus of any lens, to its proper aperture: and that the focal distances of the eye-glasses are proportional to the apertures. And M. Auzout says he found, by experience, that the apertures of telescopes ought to be nearly in the subduplicate ratio of their lengths. It has also been found by experience that object-glasses will admit of greater apertures, if the tubes be blacked within side, and their passage furnished with wooden rings.

It is to be noted, that the greater or less aperture of an object-glass, does not increase or diminish the visible area of the object; all that is effected by this, is the admittance of more or fewer rays, and consequently the appearance of the object more or less bright. But the largeness of the aperture or focal distance, causes the irregularity of its refractions. Hence, in viewing Venus through a telescope, a much less aperture is to be used than for the moon, or Jupiter, or Saturn, because her light is so bright and glaring. And this circumstance somewhat invalidates and disturbs Auzout's proportion, as is shown by Dr. Hook, *Philos. Trans. No. 4.*

APERTURE in Hydraulics. See **HYDRAULICS.**

APHELION, or APHELIUM, in Astronomy, that point in the orbit of the earth, or a planet, in which it is at the greatest distance from the sun. Which is the point α (in the fig. to the art. *ANOMALY*) or extremity of the transverse axis, of the elliptic orbit, farthest from the focus s , where the sun is placed; and diametrically opposite to the perihelion b , or nearer extremity of the same axis. In the

Ptolemaic system, or in the supposition that the sun moves about the earth, the aphelion becomes the apogee.

The times of the aphelia of the primary planets, may be known by their apparent diameter appearing the smallest, and also by their moving slowest in a given time: and the same of the moon's apogee. Calculations and methods of finding them have been given by many astronomers, as Riccioli, Almag. Nov. lib. 7, sect. 2 and 3; Wolfius, Elem. Astron. § 659; Dr. Halley, *Philos. Trans.* No. 128; Sir I. Newton, *Princip. lib. 3, prop. 14;* Dr. James Gregory, *Astron. lib. 3, prop. 14;* Keil, *Astron. Lect.*; Dela Lande, *Memoires de l'Acad. 1755, 1757, 1766,* and in his *Astron. liv. 22;* also in the writings of MM. Euler, D'Alembert, Clairaut, &c, on attraction; Vince's *Astron.*; vol. i, p. 133; and Gregory's *Astron.* p. 220.

The aphelia of the planets are not fixed; for their mutual actions on one another keep those points of their orbits in a continual motion, which is greater or less in the different planets. This motion is made in consequentia, or according to the order of the signs; and Sir I. Newton shows that it is in the sesquiplicate ratio of the distance of the planet from the sun, that is, as the square root of the cube of the distance.

The quantities of this motion, as well as the place of the aphelion for a given time, are variously given by different authors. Kepler states them, for the year 1700, in the following table.

Planets.	Aphelion.	Annual Motion.
Mercury	12° 8' 25" 30"	1' 45"
Venus	3 24 27	1 18
Mars	0 51 29	1 7
Jupiter	8 10 40	0 47
Saturn	28 3 48	1 10
The Earth	8 25 30	

By De la Hire they are given as follows, for the same year 1700.

Planets.	Aphelion.	Annual Motion.
Mercury	13° 3' 40"	1' 39"
Venus	6 56 10	1 26
Mars	0 35 25	1 7
Jupiter	10 17 14	1 34
Saturn	29 14 41	1 22

And Lalande states them as follows, for the year 1750.

Planets.	Aphelion.	Secular Motion.
Mercury	8° 13° 33'	1° 57' 40"
Venus	10 8 13	4 10 0
Mars	5 1 28	1 51 40
Jupiter	6 10 22	1 43 20
Saturn	8 29 53	2 23 20
The Earth	9 8 38	1 49 10

And for the year 1800, they are thus:

Planets.	Aphelion.	Secular Motion.
Mercury	8° 14° 20' 50"	1° 33' 45"
Venus	10 7 59	1 21 0
Mars	5 2 24	1 51 40
Jupiter	6 11 8 20	1 34 33
Saturn	8 29 4 11	1 50 7
Herschel	11 16 30 31	1 29 2

APHELLEN, the name of a bright star in the constellation Gemini.

APIRODISIUS, in Chronology, denotes the eleventh month in the Bithynian year, commencing on the 25th July in ours.

APIAN or **APPIAN** (PETER), called in Ger-

newitz, a celebrated astronomer and mathematician, was born at Leisnig or Leipsick in Misnia, 1495, and became professor of mathematics at Ingolstadt, in 1524, where he died in the year 1552, at 57 years of age.

Apian wrote treatises on many of the mathematical sciences, and greatly improved them; more especially astronomy and astrology, which in that age were much the same thing; also geometry, geography, arithmetic, &c. He particularly enriched astronomy with many instruments, and observations of eclipses, comets, &c. His principal work was the *Astronomicum Caesareum*, published in folio at Ingolstadt in 1540, and which contains a number of interesting observations, with the descriptions and divisions of instruments. In this work he predicts eclipses, and constructs the figures of them in plano. In the 2d part of the work, or the *Meteoroscopium Planum*, he gives the description of the most accurate astronomical quadrant, and its uses. To it are added observations of five different comets, viz, in the years 1531, 1532, 1533, 1538, and 1539; where he first shows that the tails of comets are always projected in a direction from the sun.

Apian also wrote a treatise on Cosmography, or Geographical Instruction, with various mathematical instruments. This work Vossius says he published in 1524, and that Gemma Frisius republished it in 1540. But Weidler says he wrote it only in 1530, and that Gemma Frisius published it at Antwerp in 1550 and 1584, with observations of many eclipses. The truth may be, that perhaps all these editions were published.

In 1533 he made, at Norimberg, a curious instrument, which from its figure he called *Folium Populi*; which, by the sun's rays, showed the hour in all parts of the earth, and even the unequal hours of the Jews.

In 1534 he published his *Inscriptiones Orbis*.

In 1540, his *Instrumentum Sinuum, sive Primi Mobi*, with 100 problems.

Beside these, Apian was the author of many other works: among which may be mentioned the Ephemerides from the year 1534 to 1570: Books upon Shadows: Arithmetical Centilogues: Books upon Arithmetic, with the Rule of Coss (Algebra) demonstrated: On Gauging: Almanacs, with astrological directions: A book on Conjunctions: Ptolemy, with very correct figures, drawn in a quadrangular form: Ptolemy's works in Greek: Books of Eclipses: the works of Azoph, a very ancient astrologer: the works of Gebre: the Perspective of Vitello: of Critical Days, and of the Rainbow: a new Astronomical and Geometrical Radius, with various uses of Sines and Chords: Universal Astrolabe of Numbers: Maps of the World, and of particular countries: &c, &c.

Apian left a son, who many years afterwards taught mathematics at Ingolstadt, and at Tubinga. Tycho has preserved (*Progymn. p. 643*) his letter to the Landgrave of Hesse, in which he gives an opinion on the new star in Cassiopeia, of the year 1572.

One of the comets observed by Apian, viz, that of 1532, had its elements nearly the same as of one observed 128 years after, viz, in 1661, by Hevelius and other astronomers; and hence Dr. Halley judged that they were the same comet, and that therefore it might be expected to appear again in the beginning of the year 1789. But it was not found that it returned at this period, though the astronomers then looked anxiously for it; and it is doubtful whether the disappointment might be owing to its passing unobserved, or to any errors in the observations

of Apian, or to its period being disturbed and greatly altered by the actions of the superior planets, &c.

APIŠ, musca, the Bee, or Fly, in Astronomy, one of the southern constellations, containing 4 stars.

APOGEE, Apogæum, in Astronomy, that point in the orbit of the sun, moon, &c, which is farthest distant from the earth. It is at the extremity of the line of the apses; and the point opposite to it is called the perige, where the distance from the earth is the least.

The ancient astronomers, considering the earth as the centre of the system, chiefly regarded the apogee and perige: but the moderns, placing the sun in the centre, change these terms for the aphelion and perihelion.—The apogee of the sun, is the same thing as the aphelion of the earth; and the perige of the sun is the same as the perihelion of the earth.

The manner of finding the apogee of the sun or moon, is shown by Ricciolius, Almag. Nov. lib. 3, cap. 24; by Wolfius in Elem. Astr. § 618; by Cassini, De la Hire, and many others: see also *Memoires de l'Academie*, the Philos. Trans. vol. 5, 47, &c.

The apogee and perige, or the higher and lower apses, would be two fixed points, if the moon, or planet, were only acted on by the single body about which they revolve in an elliptic orbit. But, by the compound actions of the other planets, those points become changed, as if the orbit itself had a motion about its lower focus. The moon, in particular, has her regular orbit about the earth disturbed, and that in an irregular manner, according to their different positions with regard to the earth.

The quantity of motion in the apogæ may be found by comparing two observations of it made at a great distance of time; converting the difference into minutes, and dividing them by the number of years elapsed between the two observations; the quotient gives the annual motion of the apogee. Thus, from an observation made by Hipparchus in the year before Christ 140, by which the sun's apogee was found $5^{\circ} 30'$ of π ; and another made by Ricciolius, in the year 1646, by which it was found $7^{\circ} 20'$ of π ; the annual motion of the apogee is found to be $1' 2''$. And the annual motion of the moon's apogee is about $1^{\circ} 10' 39'' 52''$.

But the moon's apogee moves unequally. When she is in the syzygy with the sun, it moves forwards; but in the quadratures, backwards; and these progressions and regressions are not equable, but it goes forward slower when the moon is in the quadratures, or perhaps goes retrograde; and when the moon is in the syzygy, it goes forward the fastest of all.—See the articles **APHELION, APSIS, and LAPLACE**; also Newton's Theory of the Moon, for more upon this subject, and his Princip. lib. i. pr. 43, 44, 45.

APOLLODORUS, a celebrated architect, under Trajan and Adrian, was born at Damascus, and flourished about the year of Christ 100. He had the direction of the stone bridge which Trajan ordered to be built over the Danube in the year 104, which was esteemed the most magnificent of all the works of that emperor. Adrian, one day as Trajan was discoursing with this architect on the buildings he had raised at Rome, would needs give his judgment, in which he showed that he knew nothing of the matter. Apollodorus turned upon him bluntly, and said to him, Go paint Citruls, for you are very ignorant of the subject we are talking on. Adrian at this time boasted of his painting Citruls well. This was the

first step towards the ruin of Apollodorus; a slip which he was so far from attempting to retrieve, that he even added a new offence, and that too after Adrian was advanced to the empire, on the following occasion: Adrian sent to him the plan of a temple of Venus; and though he asked his opinion, yet to show that he had no need of him, and that he did not mean to be directed by it, the temple was already built. Apollodorus wrote his opinion very freely, and remarked such essential faults in it, as the emperor could neither deny nor remedy. He showed that it was neither high enough nor large enough; that the statues in it were disproportioned to its bulk: for, said he, if the goddesses should have a mind to rise and go out, they could not do it. This put Adrian into a great passion, and prompted him to the destruction of Apollodorus. He banished him at first; then under the pretext of certain supposed crimes, of which he had him accused, he at last put him to death.

APOLLONIUS, of Perga, a city in Pamphylia, was a celebrated geometerian, who flourished in the reign of Ptolemy Euergetes, about 240 years before Christ; being about 160 years after Euclid, and 49 years later than Archimedes. He studied a long time in Alexandria under the disciples of Euclid; and afterwards he composed several curious and ingenious geometrical works, of which only his books of Conic Sections are now extant, and even these are not perfect. For it appears from the author's dedicatory epistle to Endemus, a geometerian in Pergamus, that this work consisted of 8 books; only 7 of which however have come down to us.

From the Collections of Pappus, and the Commentaries of Eutocius, it appears that Apollonius was the author of various pieces in geometry, on account of which he acquired the title of the Great Geometrician. His Conics was however the principal of them. Some have thought that Apollonius appropriated the writings and discoveries of Archimedes; Heracilius, who wrote the life of Archimedes, affirms it; though, Eutocius endeavours to refute him. But though it should be allowed a groundless supposition, that Archimedes was the first who wrote upon conics, yet as his treatise on that subject was greatly esteemed, it is highly probable that Apollonius would avail himself of the writings of that author, as well as others who had gone before him; and, upon the whole, he has the honour of explaining a difficult subject better than had been done before; having made several improvements, both in Archimedes's problems, and in Euclid. His work was doubtless the most perfect of the kind among the ancients, and in some respects even among the moderns. Before Apollonius, it had been customary, as we are informed by Eutocius, for the writers on conics to require three different kinds of cones to cut the different sections from, viz, the parabola from a right-angled cone, the ellipse from an acute, and the hyperbola from an obtuse cone; because they always supposed the sections made by a plane cutting the cones to be perpendicular to the side of them: but Apollonius cut his sections all from any one cone, by only varying the inclination or position of the cutting plane; an improvement that has been followed by all other authors since his time. But that Archimedes was acquainted with the same manner of cutting any cone, is sufficiently proved, against Eutocius, Pappus, and others, by Guido Ubaldus, in the beginning of his Commentary on the 2d book of Archimedes's *Equiponderantes*, published at Pisa in 1588.

VOL. I.

The first four books of Apollonius's Conics only have come down to us in their original Greek language; but the next three, the 5th, 6th, and 7th, in an Arabic version; and the 8th not at all. These have been commented on, translated, and published by various authors. Pappus, in his Mathematical Collections, has left some account of his various works, with notes and lemmas upon them, and particularly on the conics. And Eutocius wrote a regular elaborate commentary on the propositions of several of the books.

The first four books were badly translated by Joan. Baptista Memmius. But a better translation of them in Latin was made by Commandine, and published at Bononia in 1566;—Vossius mentions an edition of the Conics in 1650; the 5th, 6th, and 7th books being recovered by Golius.—Claude Richard, professor of mathematics in the imperial college of his order at Madrid, in the year 1632, explained, in his public lectures, the first four books of Apollonius, which were printed at Antwerp in 1635, in folio.—The Grand Duke Ferdinand the 2d, and his brother Prince Leopold de Medicis, employed a professor of the Oriental languages at Rome to translate the 5th, 6th, and 7th books into Latin. These were published at Florence in 1661, by Borelli, with his own notes, who also maintains that these books are the genuine production of Apollonius, by many strong authorities, against Mydorgius and others, who suspected that these three books were not the real production of Apollonius.

As to the 8th, some mention is made of it in a work of Golius's, where he states that it had not been translated into Arabic; because it was wanting in the Greek copies from which the Arabians translated the others. But the learned Mersenne, in the preface to Apollonius's Conics, printed in his Synopsis of the Mathematics, quotes the Arabic philosopher Aben Nedin for a work of his about the year 400 of Mahomet, in which is part of that 8th book, and who asserts that all the books of Apollonius are extant in his language, and even more than are enumerated by Pappus; and Vossius says he has read the same; De Scientiis Mathematicis, pa. 55.—A neat edition of the first four books in Latin was published by Dr. Barrow, in 4to, at London in 1675.—A magnificent edition of all the 8 books was published in folio, by Dr. Halley, at Oxford in 1710; together with the Lemmas of Pappus, and the Commentaries of Eutocius. The first four in Greek and Latin, but the latter four in Latin only, the 8th book being restored by himself.—The other writings of Apollonius, mentioned by Pappus, are,

1. The Section of a Ratio, or Proportional Sections, two books.
2. The Section of a Space, in two books.
3. Determinate Section, in two books.
4. The Tangencies, in two books.
5. The Inclinations, in two books.
6. The Plane Loci, in two books.

The contents of all these are mentioned by Pappus, and many lemmas are delivered relative to them; but none, or very little of these books themselves have descended down to the moderns. From the account however that has been given of their contents, many restorations have been made of these works, by the modern mathematicians, as follow: viz,

APONO (*PETER de*) a learned astronomer and philosopher, was born at Aponio near Padua, about the year 1250. He described the Astrolabium Planum, by which were shown the equations of the celestial houses, for any hour and minute, and for any part of the world: it was published at Venice in 1502. He acquired the name of the Conciliator, on account of a book of his, in which he reconciles the writings of the ancient philosophers and physicians; the book was published at Venice in 1483. He resided at Padua, where, from his practising medicine, and his skill in astronomy, he fell under the suspicion of magic. He died in 1316, at 66 years of age.

APOPHYGE, in Architecture, is a concave part or ring of a column, lying above or below the flat member; and it owes its origin to the ring by which the ends of wooden columns were hooped, to prevent them from splitting.

APOTOME, the remainder or difference between two lines or quantities which are only commensurable in power. Such is the difference between 1 and $\sqrt{2}$, or the difference between the side of the square and its diagonal.

The term is used by Euclid; and a pretty full explanation of such quantities is given in the tenth book of his Elements, where he distinguishes six kinds of apotomes, and shows how to find them all geometrically.

APOTOME Prima, is when the greater term is rational, and the difference of the squares of the two is a square number: as the difference $3 - \sqrt{5}$.

APOTOME Secunda, is when the less number is rational, and the square root of the difference of the squares of the two terms, has to the greater term, a ratio expressible in numbers; such is $\sqrt{18} - 4$, because the difference of the squares 18 and 16 is 2, and $\sqrt{2}$ is to $\sqrt{18}$ as $\sqrt{1}$ to $\sqrt{9}$ or as 1 to 3.

APOTOME Tertia, is when both the terms are irrational, and, as in the second, the square root of the difference of their squares, has to the greater term, a rational ratio: as $\sqrt{24} - \sqrt{18}$; for the difference of their squares 24 and 18 is 6, and $\sqrt{6}$ is to $\sqrt{24}$ as $\sqrt{1}$ to $\sqrt{4}$, or as 1 to 2.

APOTOME Quarta, is when the greater term is a rational number, and the square root of the difference of the squares of the two terms has not a rational ratio to it: as 4 - $\sqrt{3}$, where the difference of the squares 16 and 3 is 13, and $\sqrt{13}$ has not a ratio in numbers to 4.

APOTOME Quinta, is when the less term is a rational number, and the square root of the difference of the squares of the two has not a rational ratio to the greater: as $\sqrt{6} - 2$, where the difference of the squares 6 and 4 is 2, and $\sqrt{2}$ to $\sqrt{6}$ or $\sqrt{1}$ to $\sqrt{3}$ or 1 to $\sqrt{3}$ is not a rational ratio.

APOTOME Sexta, is where both terms are irrational, and the square root of the difference of their squares has not a rational ratio to the greater; as $\sqrt{6} - \sqrt{2}$; where the difference of the squares 6 and 2 is 4, and $\sqrt{4}$ to $\sqrt{6}$ or 2 to $\sqrt{6}$, is not a rational ratio.

The doctrine of apotomes, in lines, as delivered by Euclid in the tenth book, is a very curious subject, and has always been much admired and cultivated by all mathematicians who have rightly understood this part of the elements; so that Peter Ramus has greatly exposed his judgment by censuring that book.* And the first algebraical writers in Europe commonly employed a considerable portion of their works on an algebraical exposition of it, which led them to the doctrine of surd quantities; as Lucas de Burgo, Cardan, Tartalea, Stifelius, Peletarius, &c, &c. See also Pappus, lib. 4, prop. 3, and the introduce. to lib. 7. And Dr. Wallis's Algebra, pa. 109.

APOTOME, in Music, is the difference between a greater and less semitone, being expressed by the ratio of 128 to 125.

APPARENT, that which is visible, or evident to the eye, or the understanding.

APPARENT Conjunction of the planets, is when a right line, supposed to be drawn through their centres, passes through the eye of the spectator, and not through the centre of the earth.—And, in general, the apparent conjunction of any objects, is when they appear or are placed in the same right line with the eye.

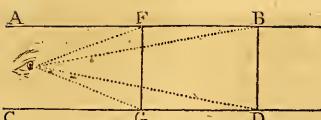

APPARENT Iitude Diameter, Distance, Horizon, Magnitude, Motion, Place, Time, &c. See the respective substantives, for the quantity and measure of it.

The apparent state of things, is commonly very different from their real state, either as to distance, figure, magnitude, position, &c, &c. Thus,

APPARENT Diameter or Magnitude, as for example of the heavenly bodies, is not the real length of the diameter, but the angle which they subtend at the eye, or under which they appear. And hence, the angle, or apparent extent, diminishing with the increased distance of the object, a very small object, as AB , may have the same apparent diameter as a very large one FG ; and indeed the objects have all the same apparent diameter, that are contained in the same angle, FEG . And if these are parallel, the real magnitudes are directly proportional to their distances.

But the apparent magnitude varies, not only by the distance, but also by the position of it. So, if the object CD be changed from the direct position, to the oblique one CED , its apparent magnitude would then be only the angle CED , instead of the angle CEG .

If the eye E be placed between two parallels AB , CD , these parallels will appear to converge, or come nearer and nearer to each other, the farther they are continued out, till at last they will appear to coincide in that point where the sight terminates, which will happen when the optic angle BED becomes equal to about one minute of a degree, the smallest angle under which a common object is distinctly visible.—Also the apparent magnitudes of the same object FG or BD , seen at different distances, that is the angles FEG , BED , are in a less ratio than the reciprocal ratio of the distances, or the distance increases in a greater ratio than the angle or apparent magnitude diminishes. But when the object is very remote, or the optic angle is very small, as one degree or thereabouts, the angle then varies nearly as the distance reciprocally.

But though the optic angle be the usual or sensible measure of the apparent magnitude of an object, yet habit, and the frequent experience of looking at distant objects, by which we know that they are larger than they appear, has so far prevailed on the imagination and judgment, as to cause this too to have some share in our estimation of apparent magnitudes; so that these will be judged to be more than in the ratio of the optic angles.

The apparent magnitude of the same object, at the same distance, is different to different persons, and different animals, and even to the same person, when viewed in different lights; all which may be occasioned by the different magnitudes of the eye, causing the optic angle to differ as that is greater or less: and since, in the same person, the more light there comes from an object, the less is the pupil of the eye, looking at that object; therefore the optic angle will also be less, and consequently the apparent magnitude of the object. Every one must have experienced the truth of this, by looking at another person in a room, and afterwards abroad in the sunshine, when he always appears smaller than in a room where the light is less. So also, objects elevated in the air, having more light coming from them than when they are upon the ground, or near it, may appear less in the former case than in the latter; thus the ball of the cross on the top of St. Paul's church, which is 6 feet in diameter, appears less than an object of the same diameter seen at the same distance below, near the ground. And this is, by some, supposed to be the reason why the sun and moon appear so much larger when seen in the horizon, where their beams are weak, than when they are more elevated, and their light stronger.

This apparent variation in the magnitude of the heavenly bodies, which is mentioned under the article *optic angle*, is a very singular phenomenon, which has engaged the attention of many eminent philosophers; and various attempts have accordingly been made to explain the cause from which it arises; the most satisfactory of which appears to be the following.

In judging of the magnitude of a body, we do not estimate it from the angle only under which we perceive it, but also from its distance, and this distance is estimated by a comparison with that of other objects. Now there is nothing between us and the moon, when she is near the zenith, from which to draw that comparison, and there-

fore, deceived by the absence of intermediate bodies, we involuntarily conclude that she is nearer to us than when we observe her rising or setting in the horizon, beyond hills, valleys, forests, and other objects, which we know to be at a considerable distance; and hence it happens, that seeing this, and the other heavenly bodies, always under the same angle, and conceiving them to be sometimes near and sometimes more remote, our senses are deceived, and we attribute to them, alternately, a greater and less magnitude.

That this is the cause of the phenomenon is demonstrable from the following circumstance, that the illusion ceases as soon as we lose sight of other objects. To prove this, it will be sufficient to observe any of the heavenly bodies through a tube, or through a small hole pierced in a card; in either case, they will appear no larger in the horizon than in the zenith, because the smallness of the aperture prevents us from seeing any other object than that on which the observation is made, and consequently all means of comparison are destroyed.

Again, if the eye be placed in a rare medium, and view an object through a denser, as glass or water, having plane surfaces; the object will appear larger than it really is: and contrariwise, smaller. And hence it is that fishes, and other objects, seen in the water, by an eye in the air, always appear larger than they are.—In like manner, an object will appear larger when viewed through a globe of glass or water, or any transparent convex spherical segment; and, on the contrary, it will appear smaller when viewed through a concave of glass or water.—See MAGNITUDE, *Apparent*; also Robins's Tracts, vol. 2, p. 225, &c.

APPARENT Distance, is that distance which we judge an object to be from us, when seen afar off. This is commonly very different from the true distance; because we are apt to think that all very remote objects, whose parts cannot well be distinguished, and which have no other visible objects near them, are at the same distance from us; though perhaps they may be thousands or millions of miles off; as in the cases of the sun and moon and stars. The apparent distances of objects are also greatly altered by the refraction of the medium through which they are seen.

APPARENT Figure, is the figure or shape which an object is seen under when viewed at a distance; and is often very different from the true figure. For a straight line, viewed at a distance, may appear but as a point; a surface, as a line; and a solid, as a surface. Also these may appear of different magnitudes, and the surface and solid of different figures, according to their situation with respect to the eye: thus, the arc of a circle may appear a straight line; a square, a trapezium, or even a triangle; a circle, an ellipsis; angular magnitudes, round; and a sphere, a circle. Also all objects have a tendency to roundness and smoothness, or appear less angular, as their distance is greater: for, as the distance is increased, the smaller angles and asperities first disappear, by subtending a less angle than one minute; after these, the next larger disappear, for the same reason; and so on continually, as the distance is more and more increased; the object seeming still more and more round and smooth. So, a triangle, or square, at a great distance, shows only as a round speck; and the edge of the moon appears round and regular to the eye, notwithstanding the hills and valleys on her surface. And hence it is also, that

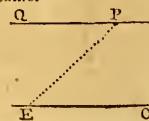

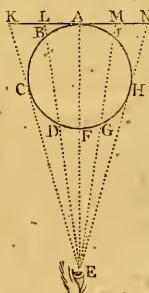

near objects, as a range of lamps, or such like, seen at a great distance, appear to be contiguous, and to form one uniform continued magnitude, by the intervals between them disappearing, from the smallness of the angles subtended by them.

APPARENT MOTION, is either that motion which we perceive in a distant body that moves, the eye at the same time being either in motion or at rest; or that motion which an object at rest seems to have, while the eye itself only is in motion.

The motions of bodies at a great distance, though really moving equally, or passing over equal spaces in equal times, may appear to be very unequal and irregular to the eye, which can only judge of them by the mutation of the angle at the eye. And motions, to be equally visible, or appear equal, must be directly proportional to the distances of the objects moving. Again, very swift motions, as those of the luminaries, may not appear to be any motions at all, but like that of the hour hand of a clock, on account of the great distance of the objects: and this will always happen, when the space actually passed over in one second of time, is less than about the 14000th part of its distance from the eye; for the hour hand of a clock, and the stars about the earth, move at the rate of 15 seconds of a degree in one second of time, which is only the 13751 part of the radius or distance from the eye. On the other hand, it is possible for the motion of a body to be so swift, as not to appear any motion at all; as when through the whole space it describes there constantly appears a continued surface of solid, as it were generated by the motion of the object, as when any thing is whirled very swiftly round, describing a ring, &c.

Also, the more oblique the eye is to the line which a distant body moves in, the more will the apparent motion differ from the true one. So, if a body revolve with an equable motion in the circumference of the circle ABCD &c, and the eye be at E in the plane of the circle; as the body moves from A to B and C, it seems to move slower and slower along the line ALK, till when the body arrives at C, it appears at rest at K; then while it really moves from C by D to F, it appears to move quicker and quicker from K by L to A, where its motion is quickest of all; after this it appears to move slower and slower from A to N, while the body moves from F to H: there becoming stationary again, it appears to return from N to A in the straight line, while its real motion is from H by I to A in the circle. And thus it appears to move in the line KN, by a motion continually varying between the least, or nothing, at the extremes K and N, and the greatest of all at the middle point A. Or, if the motion be referred to the concave side of the circle, instead of the line KN, the appearances will be the same.

If an eye move directly forwards from E to O, &c; any remote object at rest at P, will appear to move the contrary way, or from P to Q, with the same velocity. But if the object P move the same way, and

with the same velocity as the eye; it will seem to stand still. If the object have a less velocity than the eye, it will appear to move back towards Q with the difference of the velocities; and if it move faster than the eye, it will appear to move forwards from Q, with the same difference of the velocities. And so likewise when the object P moves contrary to the motion of the eye, it appears to move backwards with the sum of the motions of the two. And the truth of all this is experienced by persons sitting in a boat moving on a river, or in a wheel-carriage when running fast, and viewing houses or trees, &c, on the shore or side of the road, or other boats or wheel-carriages also in motion.

APPARENT PLACE OF AN OBJECT, in Optics, is that in which it appears, when seen in or through glass, water, or other refracting mediums; which is commonly different from the true place. So, if an object be seen in or through glass, or water, either plane or concave, it will appear nearer to the eye than its true place; but when seen through a convex glass, it appears more remote.

APPARENT PLACE OF THE IMAGE OF AN OBJECT, in Catoptrics, is that where the image of an object made by the reflection of a speculum appears to be; and the optical writers, from Euclid downwards, give it as a general rule, that this is where the reflected rays meet the perpendicular to the speculum drawn from the object: so that if the speculum be a plane, the apparent place of the image will be at the same distance behind the speculum, as the eye is before it; if convex, it will appear behind the glass nearer to the same; but if concave, it will appear before the speculum. And yet in some cases there are exceptions to this rule, as is shown by Kepler in his Paralipomena in Vitellionem, Prop. 18. See also Wolius Catopr. § 51, 188, 233, 234.

APPARENT PLACE OF A PLANET, &c, in Astronomy, is that point in the surface of the sphere of the fixed stars, where the centre of the luminary appears from the surface of the earth.

APPARITION, in Astronomy, denotes a star's or other luminary's becoming visible, which before was hid. So, the heliacal rising, is rather an apparition than a proper rising.

APPEARANCE, in Perspective, is the representation or projection of a figure, body, or the like object, on the perspective plane.—The appearance of an objective right line, is always a right line. See **PERSPECTIVE**.—Having given the appearance of an opaque body, and of a luminary, to find the appearance of the shadow; see **SHADOW**.

APPEARANCES, in Astronomy, &c, are more usually called phenomena and phases.—In Optics, the term direct appearance is used for the view or sight of any object by direct rays; without either refraction or reflection.

APPLICATE, APPLICATA, ORDINATE, in Geometry, is a right line drawn to a curve, and bisected by its diameter. This is otherwise called an **ORDINATE**; which see.

APPLICATE NUMBER. See **CONCRETE**.

APPLICATION, the act of applying one thing to another, by approaching or bringing them nearer together. So a longer space is measured by the continual application of a less; as a foot or yard by an inch, &c. And motion is determined by a successive application of any thing to different parts of space.

APPLICATION is sometimes used, both in arithmetic and geometry, for the rule or operation of division, or what is similar to it in geometry. Thus, 20 applied to,

or divided by 4, gives 5. And a rectangle ab , applied to a line c , gives the 4th proportional $\frac{ab}{c}$, or another line which, with the given line c , will contain another rectangle which shall be equal to the former rectangle ab . And this is the sense in which Euclid uses the term, lib. 6, pr. 28.

APPLICATION, in Geometry, is also used for the act or supposition of putting or placing one figure upon another, to find whether they be equal or unequal; which seems to be the primary way in which the mind first acquires both the idea and proof of equality. And in this way Euclid, and other geometers, demonstrate some of the first or leading properties in geometry. Thus, if two triangles have two sides in the one triangle equal to two sides in the other, and also the angle included by the same sides equal to each other; then are the two triangles equal in all respects: for by conceiving the one triangle placed on, or applied to the other, it is proved that they coincide or exactly agree in all their parts. And the same happens if, of two triangles, one side and the two adjacent angles of the one triangle, are equal, respectively, to one side and the two corresponding angles of the other. Thus also it may be proved that the diameter of a circle divides it into two equal parts, as also that the diagonal of a square or parallelogram bisects or divides it into two equal parts.

APPLICATION of one science to another, as of algebra to geometry, is said of the use made of the principles and properties of the one, for augmenting and perfecting the other. Indeed all arts and sciences mutually receive aid from each other. But the application here meant, is of a more express and limited nature; as will appear by what follows.

APPLICATION of Algebra or of Analysis to Geometry. The first and principal applications of algebra, were to arithmetical questions and computations, as being the first and most useful science in all the concerns of human life. Afterwards algebra was applied to geometry and all the other sciences in their turn. The application of algebra to geometry, is of two kinds; that which regards the plane or common geometry, and that which respects the higher geometry, or the nature and properties of curve lines.

The first of these, or the application of algebra to common geometry, is concerned in the algebraical solution of geometrical problems, and finding out theorems in geometrical figures, by means of algebraical investigations or demonstrations. This kind of application has been made from the time of the earliest writers, on algebra, as Diophantus, the Indians and Arabians, Lucas de Burgo, Cardan, Tartalea, &c, &c, down to the present times. Some of the best precepts and exercises of this kind of application, are to be met with in Newton's Universal Arithmetic, and in Simpson's Algebra and Select Exercises. Geometrical problems are commonly resolved more directly and easily by algebra than by the geometrical analysis, especially by young beginners; but then the synthesis, or construction and demonstration, is most elegant as deduced from the latter method. Now it commonly happens, that the algebraical solution succeeds best in such problems as respect the sides and other lines in geometrical figures; while, on the contrary, those problems in which angles are concerned, are best effected by the geometrical analysis. Newton gives these, among many other remarks on this branch. Having any problem proposed: compare together the quantities concerned in

it; and, making no difference between the known and unknown quantities, consider how they depend upon, or are related to, one another; that it may be perceived what quantities, if they are assumed, will, by proceeding synthetically, give the rest, and that in the simplest manner. And in this comparison, the geometrical figure is to be feigned and constructed at random, as if all the parts were actually known or given; and any other lines drawn that may appear to conduce to the easier and simpler solution of the problem. Having considered the method of computation, and drawn out the scheme, names are then to be given to the quantities entering into the computation, that is, to some few of them, both known and unknown; from which the rest may most naturally and simply be derived or expressed, by means of the geometrical properties of figures, till an equation be obtained, by which the value of the unknown quantity may be derived by the ordinary methods of reduction of equations, when only one unknown quantity is in the notation; or till as many equations are obtained as there are unknown letters in the same.

For example, suppose it were required to inscribe a square in a given triangle. Let ABC be the given triangle; and suppose $DEFG$ to be the required square; also draw the perpendicular BP of the triangle, which will be given, as well as all the sides of it. Then, considering that the triangles BAC , DEF are similar, it will be proper to make the notation as follows, viz, making the base $AC = b$, the perpendicular $BP = p$, and the side of the square DE or $EF = x$. Hence then $BQ = BP - ED = p - x$; consequently, by the proportionality of the parts of those two similar triangles, viz, $BP : AC :: BQ : EF$, it is $p : b :: p - x : x$; then, multiply extremes and means &c, there arises $px = bp - bx$, or $bx + px = bp$, and $x = \frac{bp}{b+p}$, the side of the square sought; that is, a fourth proportional to the base and perpendicular, and the sum of the two, taking this sum for the first term, or $AC + BP : BP :: AC : EF$.

Examp. 2. In a right-angled triangle, having given the perimeter, or sum of all the sides, and the perpendicular let fall from the right angle on the hypothenuse, to determine the sides of the triangle.

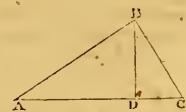

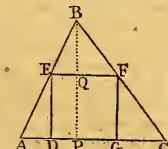

Let ABC represent the triangle, and BD the given perpendicular. Also put $BD = p$, $AB = x$, $BC = y$, $AC = z$, and the sum of the sides $= s$. Now then we have three unknown quantities, and therefore we must establish three equations before it will be possible to proceed in the solution, which are as follows;

$$x^2 + y^2 = z^2. \text{ Euclid prop. 47, book 1.}$$

$$xy = pz. \text{ Euclid prop. 8, book 4.}$$

$$x + y + z = s. \text{ By the question.}$$

From the first and second equation we find $x^2 + 2xy + y^2 = z^2 + 2pz$, or $x + y = \sqrt{(z^2 + 2pz)}$; but $x + y = s - z$, by the third equation; therefore, $\sqrt{(z^2 + 2pz)} = s - z$, or by squaring both sides and transposing $(2p + s)z = s^2$, hence $z = \frac{s^2}{2p + s}$. Having thus found the value of z , we may proceed to find x and y , and consider z as a

known quantity, only substituting in the final expressions its value determined as above. This may be done by means of any two of the original equations, but the first and second are the most proper for this purpose; from them we determine at once $x^2 + 2xy + y^2 = z^2 + 2pz$, or $x + y = \sqrt{(z^2 + 2pz)}$; $x^2 - 2xy + y^2 = z^2 - 2pz$, or $x - y = \sqrt{(z^2 - 2pz)}$; hence $x = \frac{1}{2}\sqrt{(z^2 + 2pz)} + \frac{1}{2}\sqrt{(z^2 - 2pz)}$, and $y = \frac{1}{2}\sqrt{(z^2 + 2pz)} - \frac{1}{2}\sqrt{(z^2 - 2pz)}$; and now re-establishing the value of z as determined above, the sides of the triangle will be as follows:

$$AB = \frac{s}{2}\sqrt{\left[\left(\frac{4s}{p+s}\right) + \frac{p}{p+s}\right]} + \frac{s}{2}\sqrt{\left[\left(\frac{4s}{p+s}\right) - \frac{p}{p+s}\right]};$$

$$BC = \frac{s}{2}\sqrt{\left[\left(\frac{4s}{p+s}\right) + \frac{p}{p+s}\right]} - \frac{s}{2}\sqrt{\left[\left(\frac{4s}{p+s}\right) - \frac{p}{p+s}\right]};$$

$$AC = \frac{2s^2}{p+s}.$$

The other branch of the application of algebra to geometry, was introduced by Descartes, in his Geometry, which is the new or higher geometry, and relates to properties of curve lines. In this branch, the nature of the curve is expressed or denoted by an algebraic equation, which is thus derived: A line is conceived to be drawn, as the diameter or some other principal line about the curve; and on any indefinite points of this, other lines are erected perpendicularly, which are called ordinates, while the parts of the first line cut off by them, are called abscisses. Then, calling any abscissa x , and its corresponding ordinate y , by means of the known nature, or relations of the other lines in the curve, an equation is derived, involving x and y , with other given quantities in it. Hence, as x and y are common to every point in the primary line, that equation, so derived, will belong to every position or value of the abscissa and ordinate, and so is properly considered as expressing the nature of the curve in all points of it; and is commonly called the equation of the curve.

In this way it is found that any curve line has a peculiar form of equation belonging to it, and which is different from that of every other curve, either as to the number of the terms, the powers of the unknown letters x and y , or the signs or coefficients of the terms of the equation. Thus, if the curve line HK be a circle, of which H is part of the diameter, and IK a perpendicular ordinate: then putting $HK = x$, $IK = y$, and $p =$ the diameter, the equation of the circle will be $px - x^2 = y^2$. But if HK be an ellipse, an hyperbola, or parabola, the equation of the curve will be different, and for all the four curves, will be respectively as follows, viz,

$$\text{for the circle } -px - x^2 = y^2,$$

$$\text{for the ellipse } -px - \frac{p}{t}x^2 = y^2,$$

$$\text{for the hyperbola } px + \frac{p}{t}x^2 = y^2,$$

$$\text{for the parabola } -px - t = y^2,$$

where t is the transverse axis, and p its parameter. And, in like manner for other curves. See ABSCISS.

This way of expressing the nature of curve lines, by algebraic equations, has given occasion to the greatest improvement and extension of the geometry of curve lines; for thus, all the properties of algebraic equations, and their roots, are transferred and added to curves, whose abscisses and ordinates have similar properties. Indeed the benefit of this sort of application is mutual and reciprocal, the known properties of equations being transferred

to the curves that they represent; and, on the contrary, the known properties of curves are transferred to their representative equations. See CURVES.

APPLICATION of Geometry to Algebra. Besides the use and application of the higher geometry, for obtaining the nature and roots of equations, and for finding the values of those roots by the geometrical construction of curve lines, even common geometry may be made subservient to the purposes of algebra. Thus, to take a very plain and simple instance, if it were required to square the binomial $a + b$; by forming a square, as in the annexed figure, whose side is equal to $a + b$, or the two lines or parts added together denoted by the letters a and b ; and then drawing two lines parallel to the sides, from the points where the two parts join, it will be immediately perceived that the whole square of the compound quantity $a + b$, is equal to the squares of both the parts, together with two rectangles under the two parts, or a^2 and b^2 and $2ab$, that is the square of $a + b$ is equal to $a^2 + b^2 + 2ab$, as derived from a geometrical figure or construction. And in this very manner it was, that the Arabians, and the early European writers on algebra, derived and demonstrated the common rule for resolving compound quadratic equations. And thus also, in a similar way, it was, that Tartalea and Cardan derived and demonstrated all the rules for the solution of cubic equations, using cubes and parallelopipedons instead of squares and rectangles. And many other instances might be given of the use and application of geometry in algebra.

APPLICATION of Algebra and Geometry to Mechanics. This is founded on the same principles as the application of algebra to geometry. It consists principally in representing by equations the curves described by bodies in motion, by determining the equation between the spaces which the bodies describe, when actuated by any forces, and the times employed in describing them, &c. A familiar instance also of the application of geometry to mechanics, may be seen at the article ACCELERATION, where the perpendiculars of triangles represent the times, the bases the velocities, and the areas the spaces described by bodies in motion; a method first given by Galileo. In short, as velocities, times, forces, spaces, &c, may be represented by lines and geometrical figures; and as these again may be treated algebraically; it is evident how the principles and properties, of both algebra and geometry, may be applied to mechanics, and indeed to all the other branches of mixed mathematics.

APPLICATION of Mechanics to Geometry. This consists chiefly in the use that is sometimes made of the centre of gravity of figures, for determining the contents of solids described by those figures. This is called the centrobaric method.

APPLICATION of Geometry and Astronomy to Geography. This consists chiefly in three articles. 1st, In determining the figure of the globe we inhabit, by means of geometrical and astronomical operations. 2d, In determining the positions of places, by observations of latitudes and longitudes. 3d, In determining, by geometrical operations, the position of such places as are not far distant from one another.

Geometry and Astronomy are also of great use in Navigation.

a	a^2	ab
		a

APPLICATION of Geometry and Algebra to Physics or Natural Philosophy. This application we owe to Newton, whose philosophy may therefore be called the geometrical or mathematical philosophy; and on this application are founded all the physico-mathematical sciences. Here a single observation or experiment will often produce a whole science: so, when we know, as we do by experience, that the rays of light, in reflecting, make the angle of incidence equal to the angle of reflection; we thence deduce the whole science of catoptrics: for, that experiment once admitted, catoptrics becomes a science purely geometrical, since it is reduced to the comparison of angles and lines given in position. And the same in many other sciences.

APPLICATION of one thing to another, in general, is employed to denote the use that is made of the former, to understand or to perfect the latter. Thus, the application of the cycloid to pendulums, means the use made of the cycloidal curve for improving the doctrine and use of pendulums.

APPLY. This term is used two different ways, in geometry.

1st, It signifies to transfer or place a given line, either in a circle or some other figure, so that the extremities of the line shall be in the perimeter of the figure.

2d, It is also used to express division in geometry, or to find one dimension of a rectangle, when the area and the other dimension are given. As the area ab applied to the line c , is $\frac{ab}{c}$.

APPROACH, the curve of equable approach: This was a problem first proposed by Leibnitz, namely, to find a curve, down which a body descending by the force of gravity, shall make equal approaches to the horizon in equal portions of time. It has been found by Bernoulli and others, that the curve is the second cubical parabola, placed with its vertex uppermost, and which the descending body must enter with a certain determinate velocity.—Varignon rendered the question general for any law of gravity, by which a body may approach towards a given point by equal spaces in equal times. And Maupertuis also resolved the problem in the case of a body descending in a medium which resists as the square of the velocity. See Hist. de l' Acad. des Sciences for 1699 and 1730.

Method of APPROACHES, a name given by Dr. Wallis, in his Algebra, to a method of resolving certain problems relating to square numbers, &c. This is done by first assigning certain limits to the quantities required, and then approaching nearer and nearer, till a coincidence is obtained.—In this sense, the method of Trial-and-error, or double rule of False Position, may be considered as a method of approaches.

APPROACHES, in Fortification, the several works made by the besiegers, for advancing or getting nearer to a fortress or place besieged. Such as the trenches, mines, saps, lodgments, batteries, galleries, epaulments, &c.

APPROACHES, or Lines of APPROACH, are particularly used for trenches dug in the ground, and the earth thrown up on the side towards the place besieged; under the defence or shelter of which, the besiegers may approach without loss, to raise batteries, and plant guns, &c., to batter it.—The lines of approach are commonly carried on, in a zigzag form, parallel to the opposite faces of the besieged work, or nearly so, that they may not be enfiladed by the guns from the enemy. And they are also

connected by parallels or lines of communication.—The besieged commonly make counter-approaches, to interrupt and defeat the approaches of the besiegers.

The ancients made their approaches towards the place besieged, much after the same manner as the moderns. Folard shows, that they had their trenches, their parallels, saps, &c.; which, though usually thought of modern invention, it appears, have been practised long before, by the Greeks, Romans, Asiatics, &c.

APPROXIMATION, a continual approach, still nearer and nearer, to a root or any quantity sought.—Methods of continual approximation for the square roots and cube roots of numbers, have been employed by algebraists and arithmeticians, from Lucas de Burgo down to the present time. And the later writers have given various approximations, not only for the roots of higher powers, or all simple equations, but for the roots of all sorts of compound equations whatever: especially Newton, Wallis, Raphson, Halley, De Lagny, Lagrange, &c., &c.; all of them forming a kind of infinite series, either expressed or understood, converging nearer and nearer to the quantity sought, according to the nature of the process.

It is evident that if a number proposed be not a true square, that no exact square root of it can be found, explicable by rational numbers, whether integers or fractions: therefore, in such cases, we must be content with approximations, or coming continually nearer and nearer to the truth. In like manner, for the cubic and other roots, when the proposed quantities are not exact cubes, or other powers.

The most easy and general mode of approximation, for any power above the square, is perhaps by the rule of Double Position, or, what is sometimes called, the Method of Trial-and-error; which see under its own name. And among all the rules for finding the roots of pure powers, of which there are many, I believe the best is that which was discovered by myself, and given in the first volume of my Mathematical Tracts, (printed in 1786) in point of ease, both of execution and for remembering it. Which is this: if n denote any number, out of which is to be extracted the root whose index is denoted by r ; and if n be the nearest root first taken; then will $(r+1)n + (r-1)n^r \times n$ be the required root of n very nearly; or as $r-1$ times the given number added to $r+1$ times the nearest power, is to $r+1$ times the given number added to $r-1$ times the nearest power, so is the assumed root n , to the required root, very nearly. Then this last value of the root, so found, if one still nearer is wanted, is to be used for n in the same theorem, to repeat the operation with it. And so on, repeating the operation as often as necessary. Which theorem includes all the rational formulae of Halley and De Lagny.

For example, suppose it were required to double the cube, or to find the cube root of the number 2. Here $r=3$; consequently $r+1=4$, and $r-1=2$; and therefore the general theorem becomes $\frac{4n+n^3}{2n+4n^2} \times n$ or $\frac{2n+n^3}{n+2n^2} \times n$ for the cube root of n ; or as $n+2n^3 : n^2 + n^3 : n : n$: the root sought nearly. Now, in this case, $n=2$, and therefore the nearest root n is 1, and its cube $n^3=1$ also: hence $n+2n^3=2+2=4$, and $2n+n^3=4+1=5$; therefore, as $4:5::1:\frac{1}{5}$ or $1\frac{1}{4}=1\frac{1}{25}$ the first approximation. Again, taking $r=\frac{5}{3}$ and conse-

quently $r^3 = \frac{125}{64}$;

$$\text{hence } n + 2n^2 = 2 + \frac{25}{64} = \frac{378}{64},$$

$$\text{and } 2n + n^2 = 4 + \frac{125}{64} = \frac{651}{64},$$

therefore as $378 : 381$, or as $120 : 127 :: \frac{z}{\frac{651}{64}} = 1:259921$, which is the cube root of 2, true in all the figures. And by taking $\frac{651}{64}$ for a new value of n , and repeating the process again, a great many more figures may be found.

Of the Roots of Equations by APPROXIMATION.—Stevens and Vieta gave methods for finding values, always nearer and nearer, of the roots of equations. And Oughtred and others pursued and improved the same. These however were very tedious and imperfect, and required a different process for every degree of equations. But Newton introduced, not only general methods for expressing radical quantities by approximating infinite series, but also for the roots of all sorts of compound equations whatever, which are both easy and expeditious, and which will be more particularly described under their respective articles. His method of approximating, is in substance this: First take a value of the root as near as may be, by trials, either greater or less; then assuming another letter to denote the unknown difference between this and the true value, substitute into the equation the sum or difference of the approximate root and this assumed letter, instead of the unknown letter or root of the equation, which will produce a new equation having only the assumed small difference for its root or unknown letter; and find, from this equation, a near value of this small assumed quantity. Assume then another letter for the small difference between this last value and the true one, and substitute the sum or difference of them into the last equation, by which will arise a third equation, involving the second assumed quantity; whose value is found as before. Proceeding thus as far as we please, all the near values, connected together by their proper signs, will form a series approaching still nearer and nearer to the true root of the first or proposed equation. The approximate values of the several small assumed differences, may be found in different ways: Newton's method is this: As the quantity sought is small, its higher powers decrease more and more, and therefore neglecting them will not lead to any great error. He therefore neglects all the terms having in them the 2d and higher powers, leaving only the 1st power and the absolute known term; from which simple equation he always finds the value of the assumed unknown letter nearly, in a very simple and easy manner. Halley's method of doing the same thing, was to neglect all the terms above the square or 2d power, and then to find the root of the remaining quadratic equation; which would indeed be a nearer value of the assumed letter than Newton's was, but then it is much more troublesome to perform.—Raphson has another way, which is a little varied from that of Newton's again, which is this: Having found a near value of the first assumed small quantity or difference, by this he corrects the first approximation to the root of the proposed equation; and then, assuming another letter for the next, or smaller difference, he introduces it into the original equation in the same way as before. And thus he proceeds, from one correction to another, employing always the first proposed equation to find them, instead of the successive new equations used by Newton.

For example, let it be required to find the root of the equation $x^3 - 5x = 31$, or $x^3 - 5x - 31 = 0$:—Here the root x , it is evident, is nearly $= 8$; for x therefore take $8 + z$, and substitute $8 + z$ for x in the given equation

and the terms will be thus;

$$x^3 = 64 + 16z + z^3$$

$$- 5x = - 40 - 5z$$

$$- 31 = - 31$$

$$\text{the sum is } - 7 + 11z + z^3 = 0,$$

Then, rejecting z^3 , it is $11z - 7 = 0$, and $z = \frac{7}{11} = .6363$, &c., or $= .6$ nearly.

Assume now $z = .6 + y$; then

$$z^3 = 36 + 12y + y^3$$

$$11z = 6.6 + 11y$$

$$- 7 = - 7$$

$$\text{the sum } - 0.4 + 12.2y + y^3 = 0,$$

$$\text{where } y = \frac{-0.4}{12.2} = .003278 \text{ nearly.}$$

Hence, then, collecting all the assumed differences, with their signs, it is found that $x = 8 + z + y = 8 + .6 + .003278 = 8.603278$ the root of the equation required, by Newton's method.

The same by Raphson's way.

$$\text{First } x = 8 + z;$$

$$\text{then } x^3 = 64 + 16z + z^3$$

$$- 5x = - 40 - 5z$$

$$- 31 = - 31$$

$$\text{the sum } - 7 + 11z + z^3 = 0;$$

$$\text{hence } z = \frac{7}{11} = .6 \text{ nearly, as before,}$$

$$\text{and } x = 8 + z = 8.6 \text{ nearly.}$$

Assume it $x = 8.6 + y$;

$$\text{then } x^3 = 73.96 + 17.2y + y^3$$

$$- 5x = - 43 - 5y$$

$$- 31 = - 31$$

$$\text{the sum } - 0.4 + 12.2y + y^3 = 0;$$

$$\text{hence } y = \frac{-0.4}{12.2} = .003278 \text{ nearly,}$$

$$\text{and } x = 8.6 + y = 8.603278, \text{ as before.}$$

And in the same manner Newton performs the approximation for the roots of literal equations, that is, equations having literal coefficients; so the root of this equation

$$y^3 + axy + a^2y - x^3 - 2x^2 = 0, \text{ is}$$

$$y = a - \frac{x}{4} + \frac{x^2}{64a} + \frac{131x^3}{512a^2} + \frac{509x^4}{16384a^3} \text{ &c.}$$

See also a memoir on this method by the Marquis de Courtivron, in the Mémoires de l'Academie for 1744.

Other Methods of APPROXIMATION. Besides the foregoing general methods, other particular ways of approximating, for various purposes, have been given by many different persons.—As for example, methods of approximating, by series, to the roots of cubic equations belonging to the irreducible case, by Nicole in the same Mémoires de l'Academie, by M. Clairaut in his Algebra, and by myself in the Philos. Trans. for 1780. See also several parts of Simpson's works, or my Tracts vol. 1, and my Course of Mathematics, vol. 1; or the treatise on numerical equations by Lagrange. Also the methods of infinite series by Wallis, Newton, Gregory, Mercator, &c., may be considered as approximations, in quadratures, and other branches of the mathematics, many instances of which may be seen in Wallis's Algebra, and other books:—Likewise the method of exhaustions of the ancients, by which Archimedes and others have approximated to the quadrature and rectification of the circle, &c., which was performed by continually bisecting the sides of polygons, both inscribed in a circle and circumscribed about it; by which means the sum of the sides of the like polygons approach continually nearer and nearer together, and the circumference of the circle is nearly a mean between the two sums. See also EQUATIONS.

APPULSE, in Astronomy, means the near approach of two luminaries to each other, so as to be seen, for instance, within the same telescope.

The appulses of the planets to the fixed stars have always been very useful to astronomers, as serving to fix and determine the places of the former. The ancients, wanting an easy method of comparing the planets with the ecliptic, which is not visible, had scarce any other way of fixing their situations, but by observing their track among the fixed stars, and marking their appulses to some of those visible points. See Hist. Acad. Scien. for 1710, pa. 417. And Philos. Trans. No. 369; where Dr. Halley has given method for determining the places of the planets, by observing their near appulses to the fixed stars. See also Philos. Trans. No. 76, pa. 361, and Mem. Acad. Scien. for 1708, where Flamsteed and De la Hire have given observations of the moon's appulses to the Pleiades. See also Flamsteed's Historia Cœlestis, where a multitude of observations of appulses, or small distances, of the moon and planets, from the fixed stars, are recorded. And Dr. Halley has published a map or planisphere of the starry zodiac, in which are accurately laid down all the stars to which the moon's appulse has ever been observed in any part of the world. See Philos. Trans. No. 369; or my Abridg. vol. 6, pa. 530.

APRIL, the 4th month of the year according to the common computation, and the 2d from the vernal equinox.—The word is derived from *Aprilis*, of *aperio*, *I open*; because the earth, in this month, begins to open her bosom for the production of vegetables.—In this month the sun travels through part of the signs Aries and Taurus.

APRON, in Gunnery, a piece of thin or sheet lead, used to cover the vent or touch-hole of a cannon.

APSES, or APSIDES, in Astronomy, are the two points in the orbits of planets, where they are at their greatest and least distance from the sun or the earth. The point at the greatest distance being called the higher apsis, and that at the nearest distance the lower apsis. Also the higher apsis is more particularly called the aphelion, or the apogee; and the lower apsis, the perihelion, or the perigeo. The diameter which joins these two points, is called the line of the apses or of the apsidies; it passes through the centre of the orbit of the planet, and the centre of the sun or the earth; and in the modern astronomy this line makes the longer or transverse axis of the elliptical orbit of the planet. In this line is counted the eccentricity of the orbit; being the distance between the centre of the orbit and the focus, where is placed the sun or the earth.

The foregoing definitions suppose the lines of the greatest and least distances to lie in the same straight line; which is not always precisely the case; as they are sometimes out of a right line, making an angle greater or less than 180 degrees, and the difference from 180 degrees is called the motion of the line of the apses: when the angle is less than 180 degrees, the motion of the apses is said to be contrary to the order of the signs; on the other hand, when the angle exceeds 180 degrees, the motion is according to the order of the signs.

Different means have been employed to determine the motion of the apses. Dr. Keil explains, in his Astronomy, the method used by the ancients, who supposed the orbits of the planets to be perfectly circular, and the sun out of the centre. But since it has been discovered that they describe elliptic orbits, various other methods have been devised for determining it. Dr. Halley has given one,

VOL. I.

which supposes to be known only the time of the planet's revolution, or periodic time. Seth Ward has also given a determination from three different observations of a planet, in any three places of its orbit; but his method being founded on an hypothesis not strictly true, Euler has given one much more exact in vol. 7 of the Petersburg Commentaries. See various ways explained in the Astronomy of Keil and Monnier.

Newton has also given, in the Principia, an excellent method for determining the same motion, on the supposition that the orbits of the planets differ but little from circles, which is the case nearly. That great philosopher shows, that if the sun be immovable, and all the planets gravitate towards him in the inverse ratio of the squares of their distances, then the apses will be fixed, or their motion nothing; that is, the lines of greatest and least distance will form one right line, and the apses will be directly opposite, or at 180 degrees distance from each other. But, because of the mutual tendency of the planets towards each other, their gravitation towards the sun is not precisely in that ratio; and hence it happens, that the apses are not always exactly in a right line with the sun. And Newton has given a very elegant method of determining their motion, on the supposition that we know the force which is thereby added to the gravitation of the planet towards the sun, and that this additional force is always in that direction. Dr. Chas. Walmesley has a treatise on the Théorie du Mouvement des Apsides, in 8vo.

APSIS. See APSES.

APUS or APOUS, Avis Indica, in Astronomy, a constellation of the southern hemisphere, situated near the south pole, between the triangulum australe and the chameleon, and supposed to represent the bird of paradise. Also supposed to be one of the birds named Apodes, as having no feet.

The number of stars contained in this constellation are, 11 in the British Catalogue, in Bayer's Maps 12, and a still greater number in Le Caille's Catalogue; the principal star being but of the 4th or 5th order of magnitude. See Coelum Australe Stelliferum, and the Mémoires de l'Acad. for 1752, pa. 569.

AQUARIUS, in Astronomy, one of the celestial constellations, being the eleventh sign in the zodiac, reckoning from Aries, and is marked by the character $\text{\texttt{m}}$, representing part of a stream of water, issuing from the vessel of Aquarius, or the water-pourer. This sign also gives name to the eleventh part of the ecliptic, through which the sun moves in part of the months of January and February.

The poets feign that Aquarius was Gauymede, whom Jupiter ravished under the shape of an eagle, and carried away into Heaven to serve as a cup-bearer, instead of Hebe and Vulcan; whence the name. Others hold, that the sign was thus called, because that when it appears in the horizon, the weather commonly proves rainy.

The stars in the constellation Aquarius are, in Ptolemy's Catalogue 45, in Tycho's 41, in Hevelius's 47, and in Flamsteed's 108. See the article CONSTELLATION; also CATALOGUE.

AQUEDUCT, or AQUÆDUCT, that is to say, ductus aquæ, a conduit of water, is a construction of stone or timber built on uneven ground, to preserve the level of water, and convey it, by a canal, from one place to another.—Some aqueducts are under ground, being conducted through hills, &c.; and others are raised above ground, and supported on arches, to conduct the water over valleys, &c.

T

The Romans were very magnificent in their aqueducts; having some that extended a hundred miles, or more. Frontinus, a man of consular dignity, who had the direction of the aqueducts under the emperor Nerva, speaks of nine that emptied themselves through 13,594 pipes, of an inch diameter. And it is observed by Vigenere, that in the space of 24 hours, Rome received from these aqueducts not less than 500,000 hogheads of water. The chief aqueducts now in being, are these: 1st, that of the Aqua Virginea, repaired by pope Paul IV; 2d, the Aqua Felice, constructed by pope Sixtus V, and is called from the name he assumed before he was exalted to the papal throne; 3d, the Aqua Paulina, repaired by pope Paul V, in the year 1611; and 4thly, the aqueduct built by Louis XIV, near Maintenon, to convey the river Bure to Versailles, which is perhaps the largest in the world; being 7000 fathoms long, elevated 2560 fathoms in height, and containing 242 arcades. See Philos. Trans. for 1685, No. 171; or my Abridg. vol. 3, pa. 167 and 231.

AQUEOUS HUMOUR, or the watry humour of the eye, is the first or outermost, and the rarest of the three humours of the eye. It is transparent and colourless, like water; and it fills up the space that lies between the cornea tunica, and the crystalline humour.

AQUILA, the *Eagle*, or the *Vulture* as it is sometimes called, is a constellation of the northern hemisphere, usually joined with Antinous. It is one of the 48 old constellations, according to the division of which Hipparchus made his Catalogue of the Fixed Stars, and which are described by Ptolemy. The number of stars in Aquila, and those near it, now in the later-formed constellation Antinous, amount to 15 in Ptolemy's Catalogue, to 19 in Tycho's, to 42 in that of Hevelius, and to 71 in Flamsteed's. But in Aquila alone, Tycho counts only 12 stars, and Hevelius 23; the principal star being Lucida Aquila, and is between the 1st and 2d magnitude. The Greeks, as usual, relate various fables of this constellation, to make the science appear as of their own invention.

ARA, the *Altar*, one of the 48 old constellations, mentioned by the ancient astronomers, and is situated in the southern hemisphere; containing only 7 stars in Ptolemy's Catalogue, and 9 in that of Flamsteed; none of which exceed the 4th magnitude.

ARATUS, celebrated for his Greek poem entitled *Φαινόντα*, the *Phenomena*, flourished about the 127th Olympiad, or near 300 years before Christ, while Ptolemy Philadelphus reigned in Egypt. Being educated under Diogenes Heracloteos, a Stoic philosopher, he espoused the principles of that sect, and became physician to Antigonus Gonatas, the son of Demetrios Poliorcetes, king of Macedon. The *Phenomena* of Aratus gives him a title to the character of an astronomer, as well as a poet. In this work he describes the nature and motion of the stars, and shows their various dispositions and relations; he describes the figures of the constellations, their situations in the sphere, the origin of the names which they bear in Greece and in Egypt, the fables which have given rise to them, the rising and setting of the stars, and he indicates the manner of knowing the constellations by their respective situations.

The poem of Aratus has been commented on and translated by many authors: of whom, among the ancients, were Cicero, Germanicus Caesar, and Festus Avienus, who made Latin translations of it; a part of the former of which is still extant. Aratus must have been much es-

teemed by the ancients, since we find so great a number of scholiasts and commentators on him; among whom are Aristarchus of Samos, the Arystylli the geometricians, Apollonius, the Eveneti, Crates, Numenius the grammarian, Pyrrhus of Magnesia, Thales, Zeno, and many others, as may be seen in Vossius, p. 156. Suidas ascribes several other works to Aratus. Virgil, in his Georgics, has translated or imitated many passages from this author: Ovid speaks of him with admiration, as well as many others of the poets. And St. Paul has quoted a passage from him; which is in his speech to the Athenians (Acts xvii. 28.) where he tells them that some of their own poets have said, "For we are also his offspring," these words being the beginning of the 5th line of the *Phenomena* of Aratus.

His modern editors are as follow: Henry Stephens published his poem at Paris in 1566, in his collection of the poets, in folio. Grotius published an edition of the *Phenomena* at Leyden in quarto, 1600, in Greek and Latin, with the fragments of Cicero's version, and the translations of Germanicus and Avienus; all which the editor has illustrated with curious notes. Also a neat and correct edition of Aratus was published at Oxford, 1672, in 8vo. with the Scholia.

ARÆOMETER, see AREOMETER.

ARC, or ARCH; which see.

ARCADE, in Architecture, denotes an opening in the wall of a building formed by an arch.

ARC-BOUTANT, is a kind of arched buttress, formed of a flat arch, or part of an arch, abutting against the feet, or sides of another arch or vault, to support them and prevent them from bursting or giving way.

ARCH, Arc, Arcus, in Geometry, a part of any curve line; as, of a circle, or ellipsis, or the like.

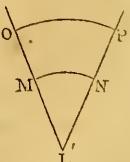

It is by means of circular arcs, or arches, that all angles are measured; the arc being described from the angular point as a centre. For this purpose, every circle is supposed to be divided into 360 degrees, or equal parts; and an arch, or the angle it subtends and measures, is estimated according to the number of those degrees it contains: thus, an arc, or angle, is said to be of 30 or 80, or 100 degrees. Of late years the French mathematicians have divided the circle into 400 degrees, or the quadrant into 100, called the centigrade division. Circular arcs are also of great use in finding of fluents.

Concentric Arcs, are such as have the same centre.

Equal Arcs, are such arcs, of the same circle, or of equal circles, as contain the same number of degrees. These have also equal chords, sines, tangents, &c.

Similar Arcs, of unequal circles, &c., are such as contain the same number of degrees, or that are the like part or parts of their respective whole circles. Hence, in concentric circles, any two radii cut off, or intercept, similar arcs MN and OP.—Similar arcs are proportional to the radii LM, LO, or to the whole circumferences.—Similar arcs of other like curves, are also like parts of the wholes, or determined by like parts similarly posited.

Of the Length of Circular Arcs. The lengths of circular arcs, as found and expressed in various ways, may be seen in my large Treatise on Mensuration, pa. 88 et seq. 4th edition: some of which are as follow. The radius of a circle being 1; and of any arc a , if the tangent be t , the sine s ,

$$\begin{aligned} \text{the cosine } c, \text{ and the versed sine } v: \text{ then the arc } a \text{ will be} \\ \text{truly expressed by several series, as follow, viz, the arc} \\ a = t - \frac{1}{3}t^3 + \frac{1}{5}t^5 - \frac{1}{7}t^7 + \frac{1}{9}t^9 \&c. \\ a = \frac{s}{c} - \frac{1}{3} \cdot \frac{s^3}{c^3} + \frac{1}{5} \cdot \frac{s^5}{c^5} - \frac{1}{7} \cdot \frac{s^7}{c^7} \&c. \\ a = s + \frac{1}{2 \cdot 3} s^3 + \frac{1 \cdot 3}{2 \cdot 4 \cdot 5} s^5 + \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6 \cdot 7} s^7 \&c. \\ a = \sqrt{2v} \times \left(1 + \frac{1}{2 \cdot 3} \cdot \frac{v}{2} + \frac{1 \cdot 3}{2 \cdot 4 \cdot 5} \frac{v^2}{2^2} + \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6 \cdot 7} \frac{v^3}{2^3}\right) \&c. \\ a = \frac{3^{14159} \cdot c}{150} d = 0.01745329 \&c \times d; \text{ where } d \text{ denotes} \end{aligned}$$

the number of degrees in the given arc. Also $a = \frac{sc - c}{3}$ nearly; where c is the chord of the arc, and s the chord of half the arc; whatever the radius is.

To find the length of the arc of any curve. Put x = the absciss, y = the ordinate, of the arc z , of any curve whatever. Put $\hat{z} = \sqrt{(x^2 + y^2)}$; then, by means of the equation of the curve, find the value of \dot{x} in terms of \dot{y} , or of \dot{y} in terms of \dot{x} , and substitute that value instead of it in the above expression $\hat{z} = \sqrt{(x^2 + y^2)}$; hence, taking the fluents, they will give the length of the arc z , in the terms of x or y .

Arc, in Astronomy. Of this, there are various kinds. Thus, the latitude, elevation of the pole, and the declination, are measured by an arc of the meridian; and the longitude, by an arc of a parallel circle, &c.

Diurnal Arc of the sun, is part of a circle parallel to the equator, described by the sun in his course from his rising to the setting. And his Nocturnal Arc is of the same kind; excepting that it is described from setting to rising.

Arc of Progression, or Direction, is an arch of the ecliptic, which a planet seems to pass over, when its motion is direct, or according to the order of the signs.

Arc of Retrogradation, is an arch of the ecliptic, described while a planet is retrograde, or moves contrary to the order of the signs.

Arc between the Centres, in eclipses, is an arc passing from the centre of the earth's shadow, perpendicular to the moon's orbit, meeting her centre at the middle of an eclipse.—If the aggregate of this arc and the apparent semi-diameter of the moon, be equal to the semi-diameter of the shadow, the eclipse will be total for an instant, or without any duration; and if that sum be less than the radius of the shadow, the eclipse will be total, with some duration; but if greater, the eclipse will be only partial.

Arc of Vision, is that which measures the sun's depth below the horizon, when a star, before hid by his rays, begins to appear again.—The quantity of this arc is not always the same, but varies with the latitude, declination, right ascension, or descension, and distance, of any planet or star. Ricciol. Almag. vol. 1, pa. 42. However, the following numbers will serve nearly for the stars and planets.

TABLE exhibiting the *Arc of Vision* of the PLANETS and FIXED STARS.

PLANETS.	FIXED STARS.	Magnitude.				
Mercury	- - -	10° 0'	1	-	-	120
Venus	- - -	5° 0'	2	-	-	13
Mars	- - -	11° 30'	3	-	-	14
Jupiter	- - -	10° 0'	4	-	-	15
Saturn	- - -	11° 0'	5	-	-	16
			6	-	-	17

Arch, in Architecture, is a concave structure, raised or turned upon a mould, called the centering, in form of the arch of a curve, and serving as the inward support of

some superstructure. Sir Henry Wotton says, An arch is nothing but a narrow or contracted vault; and a vault is a dilated arch.

Arches are used in large intercolumniations of spacious buildings; in porticos, both within and without temples; in public halls, as ceilings, the courts of palaces, cloisters, theatres, and amphitheatres. They are also used to cover the cellars in the foundations of houses, and powder magazines; also as buttresses and counter-forts, to support large walls laid deep in the earth; for triumphal arches, gates, windows, &c; and, above all, for the foundations of bridges and aqueducts. And they are supported by piers, butments, imposts, &c.

Arches are of several kinds, and are commonly denominated from the figure or curve of them; as circular, elliptical, cycloidal, catenarian, &c, according as their curve is in the form of a circle, ellipse, cycloid, catenary, &c.

There are also other denominations of circular arches, according to the different parts of a circle, or manner of placing them. Thus,

Semicircular ARCHES, which are those that make an exact semicircle, having their centre in the middle of the span or chord of the arch; called also by the French builders, perfect arches, and arches en plein centre. The arches of Westminster Bridge are semicircular.

Scheme ARCHES, or skene, are those which are less than semicircles, and are consequently flatter arches, containing 120, or 90, or 60, degrees, &c. They are also called imperfect and diminished arches.

ARCHES of the third and fourth point, or Gothic arches; or, as the Italians call them, *di terzo* and *quarto acuto*, because they always meet in an acute angle at top. These consist of two excentric circular arcs, meeting in an angle above, and are drawn from the division of the chord into three or four more parts at pleasure. Of this kind are many of the arches in churches and other old Gothic buildings.

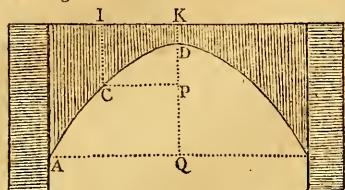

Elliptical ARCHES, usually consist of semi-ellipses. These were formerly much used instead of mantle-trees in chimneys; and are still employed, from their bold and beautiful appearance, for many purposes, and particularly for the arches of a bridge, like that at Black-Friars, both for their strength, beauty, convenience, and cheapness.

Straight ARCHES, are those which have their upper and under edges parallel straight lines, instead of curves. These are chiefly used over doors and windows; and have their ends and joints usually pointing towards one common centre.

ARCN is particularly used for the space between the two piers of a bridge, intended for the passage of the water, boats, &c.

Arch of equilibration, is that which is in equilibrium in all its parts, having no tendency to break in one part more than in another, and which is therefore safer and stronger than any other figure. Every particular figure of the extrados, or upper side of the wall above an arch, requires a peculiar curve for the under side of the arch itself, to form an arch of equilibration, so that the incumbent pressure on every part may be proportional to the strength or resistance there. When the arch is equally thick throughout, a case that can hardly ever happen, then the catenarian curve is the arch of equilibration; but in no other case: and therefore it is a great mistake in some authors to suppose that this curve is the best figure for arches in all cases; when in reality it is commonly the

worst. This subject is fully treated in my Collection of Tracts, tract 1, on the Principles of Bridges, pr. xi, exam. 2, where the proper intrados is investigated for every extrados, so as to form an arch of equilibration in all cases whatever. It there appears that, when the upper side of wall is a straight horizontal line, as in the annexed figure,

the equation of the curve is thus expressed,

$$\text{KI or PC} = y = h \times \frac{\log. \frac{w + \sqrt{(w^2 - a^2)}}{a}}{\log. \frac{c + \sqrt{(c^2 - a^2)}}{a}};$$

where $h = AQ$, $w = cr$, $a = DK$, $c = KQ$.

$$\text{Or } cr = w = \frac{a^2 + n^2}{2n}; \quad n = \text{the number whose log. is } cy + a, \text{ and } a = \log. \text{ of } a, \text{ and } c = \frac{1}{h} \times \log. \frac{c + \sqrt{(c^2 - a^2)}}{a}.$$

And hence, when a , h , c , are any given numbers, a table is formed for the corresponding values of w and y , by which the curve is constructed for any particular occasion. Thus supposing a or $DK = 6$, h or $AQ = 50$, and c or $KQ = 46$; then the corresponding values of KI or IC , or horizontal and vertical lines, will be as in this table.

Table for constructing the Curve of Equilibration.

Value of KI.	Value of IC.	Value of KI.	Value of IC.	Value of KI.	Value of IC.
0	6'000	21	10'381	36	21'774
2	6'035	22	10'858	37	22'948
4	6'144	23	11'368	38	24'190
6	6'324	24	11'911	39	25'505
8	6'580	25	12'489	40	26'894
10	6'914	26	13'106	41	28'364
12	7'330	27	13'761	42	29'919

See my Tracts, vol. i, art. 1.

The doctrine and use of arches are neatly delivered by sir Henry Wotton, though he is not always mathematically accurate in the principles. He says; 1st, All matter, unless impeded, tends to the centre of the earth in a perpendicular line. 2d, All solid materials, as bricks, stones, &c, in their ordinary rectangular form, if laid in numbers, one by the side of another, in a level row, and their extreme ones sustained between two supporters; those in the middle will necessarily sink, even by their own gravity, much more if forced down by any superincumbent weight. To make them stand, therefore, either their figure or their position must be altered.—3d, Stones, or other materials, being figured cuneatim, or wedge-like, broader above than below, and laid in a level row, with their two extremes

supported as in the last article, and pointing all to the same centre; none of them can sink, till the supporters or butments give way, because they want room in that situation to descend perpendicularly. But this is a weak structure; because the supporters are subject to too much impulsion, especially where the line is long; for which reason the form of straight arches is seldom used, excepting over doors and windows, where the line is short, and the side walls strong. In order to fortify the work, therefore, we must change not only the figure of the materials, but also their position.—4th, If the materials be shaped wedge-like, and be disposed in form of an arch, and pointing to some centre; in this case, neither the pieces of the said arch can sink downwards, for want of room to descend perpendicularly; nor can the supporters or butments suffer much violence, as in the preceding flat form: for the convexity will always make the incumbent rather rest upon the supporters, than thrust or push them outwards. His reasoning, however, afterwards, on the effect of circular and other arches, is not accurate, as he attends only to the side pressure, without considering the effect of different vertical pressures.

The chief properties of arches of different curves may be seen in the 2d sect. of my Tract on the Principles of Bridges, above quoted. It there appears that none, except the mechanical curve of the arch of equilibration, can admit of a horizontal line at top: that this arch is of a form both graceful and convenient, as it may be made higher or lower at pleasure, with the same span or opening: that all other arches require extrados that are curved, more or less, either upwards or downwards: of these, the elliptical arch approaches the nearest to that of equilibration, for equality of strength and convenience; and it is also the best form for most bridges, as it can be made of any height to the same span, its hanches being at the same time sufficiently elevated above the water, even when it is very flat at top: elliptical arches also look bolder and lighter, are more uniformly strong, and much cheaper than most others, as they require less materials and labour. Of the other curves, the cycloidal arch is next in quality to the elliptical one, for those properties, and lastly the circle. As to the others, the parabola, hyperbola, and catenary, they are quite inadmissible in bridges that consist of several arches; but may, in some cases, be employed for a bridge of one single arch, which may be intended to rise very high, as in such cases they are not much loaded at the hanches.

See also BRIDGE, and MAGAZINE.

ARCH Mural. See MURAL ARCH.

ARCHER, or Sagittarius, one of the constellations of the northern hemisphere, and one of the twelve signs of the zodiac, placed between the Scorpion and Capricorn. See SAGITTARIUS.

ARCHIMEDES, one of the most celebrated mathematicians among the ancients, who flourished about 280 years before Christ, being about 110 years later than Euclid. He was born at Syracuse in Sicily, and was related to Hiero, according to Plutarch, the then king of that city, by his father. In his youth, he devoted himself to the study of geometry; and in his mature years, he travelled into Egypt, whither the Greeks usually resorted in the pursuit of science. After an absence of several years, which he spent in the society of Conon and other eminent men, and during which time he gave very promising indications of his future fame, he returned to his own country; and

then continued his studies with the greatest assiduity. Such indeed were the ardour and intencness of his application to mathematical science, that he prosecuted his studies to the neglect both of food and sleep, and improved the minutest circumstance that occurred into an occasion of making very important and useful discoveries. The mathematical genius of Archimedes set him with such distinguished excellence in the view of the world, as rendered him both the honour of his own age, and the admiration of posterity. He was indeed the prince of the ancient mathematicians, being to them what Newton is to the moderns, to whom in his genius and character he bears a very near resemblance. He was frequently lost in a kind of reverie, so as to appear hardly sensible; he would study for days and nights together, neglecting his food; and Plutarch tells us that he used to be carried, to the baths by force. Many particulars of his life, and works, mathematical and mechanical, are recorded by several of the ancients, as Polybius, Livy, Plutarch, Pappus, &c. He was equally skilled in all the sciences, astronomy, geometry, mechanics, hydrostatics, optics, &c, in all of which he excelled, and made many and great discoveries.

Archimedes, it is said, made a sphere of glass, of a most surprising contrivance and workmanship, exhibiting the motions of the heavenly bodies in a very pleasing manner. Claudian has an epigram on this invention, which has been thus translated:

When in a glass's narrow space confin'd,
Jove saw the fabric of th' almighty mind,
He smil'd, and said, Can mortals' art alone,
Our heavenly labours mimic with their own?
The Syracusan's brittle work contains
Th' eternal law, that through all nature reigns.
Fram'd by his art, see stars unnumber'd burn,
And in their courses rolling orbs return:
His sun through various signs describes the year;
And every month his mimic moons appear.
Our rival's laws his little planets bind,
And rule their motions with a human mind.
Salmoneus could our thunder imitate,
But Archimedes can a world create.

Many wonderful stories are told of his discoveries, and of his very powerful and curious machines, &c. Hiero once admiring them, Archimedes replied, these effects are nothing, "But give me," said he, "some other place to fix a machine on, and I will move the earth." He fell upon a curious device for discovering the deceit which had been practised by a workman, employed by the king to make a golden crown. Hiero, having a mind to make an offering to the gods of a golden crown, agreed for one of great value, and weighed out the gold to the artificer. After some time he brought the crown home of the full weight; but it was afterwards discovered or suspected that a part of the gold had been stolen, and the like weight of silver substituted in its stead. Hiero, being angry at this imposition, desired Archimedes to take it into consideration, how such a fraud might be certainly discovered. While engaged in the solution of this difficulty, he happened to go into the bath; where observing that a quantity of water overflowed, equal to the bulk of his body, it presently occurred to him, that Hiero's question might be answered by a like method: upon which he leaped out, and ran homeward, crying out Εὗρηκα! εὗρηκα! I have found it! I have found it! He then made two masses, each of the same weight as the crown, one of gold and the other of silver;

this done, he filled a vessel to the brim with water, and put the silver mass into it, upon which a quantity of water overflowed equal to the bulk of the mass; then taking the mass of silver out he filled up the vessel again, measuring the water exactly, which he put in; this showed him what measure of water answered to a certain quantity of silver. He then tried the gold in like manner, and found that it caused a less quantity of water to overflow, the gold being less in bulk than the silver, though of the same weight. He then filled the vessel a third time, and putting in the crown itself, he found that it caused more water to overflow than the golden mass of the same weight, but less than the silver one; so that, finding its bulk between the two masses of gold and silver, and that in certain known proportions, he hence computed the real quantities of gold and silver in the crown, and so manifestly discovered the fraud.

Archimedes also contrived many machines for useful and beneficial purposes; among these, engines for launching large ships; screw pumps, for exhausting the water out of ships, marshes, or overflowed lands, as Egypt, &c, which they would do from any depth.

But he became most famous by his curious contrivances, by which the city of Syracuse was so long defended, when besieged by the Roman consul Marcellus; showering upon the enemy sometimes long darts, and stones of vast weight, and in great quantities; at other times lifting their ships up into the air, that had come near the walls, and dashing them to pieces by letting them fall down again; nor could they find their safety in removing out of the reach of his cranes and levers, for there he contrived to fire them with the rays of the sun reflected from burning glasses.

However, notwithstanding all his art, Syracuse was at length taken by storm, or by corrupting the guards. "What gave Marcellus the greatest concern," says Plutarch, "was the unhappy fate of Archimedes, who was at that time in his museum; and his mind, as well as his eyes, so fixed and intent upon some geometrical figures, that he neither heard the noise and hurry of the Romans, nor perceived the city to be taken. In this depth of study and contemplation, a soldier came suddenly upon him, and commanded him to follow him to Marcellus; which he refusing to do, till he had finished his problem, the soldier, in a rage, drew his sword, and ran him through." Livy says he was slain by a soldier, not knowing who he was, while he was drawing schemes in the dust: that Marcellus was grieved at his death, and took care of his funeral; and made his name a protection and honour to those who could claim a relationship to him. His death it seems happened about the 142d or 143d Olympiad, or 210 years before the birth of Christ. According to Tzetzes he lived 75 years.

When Cicero was questor for Sicily, he discovered the tomb of Archimedes, all overgrown with bushes and brambles; which he caused to be cleared, and the place set in order. There was a sphere and cylinder cut upon it, with an inscription, but the latter part of the verses quite worn out.

Many of the works of this great man are still extant, though the greatest part of them are lost. The pieces remaining are as follow: 1. Two books on the Sphere and Cylinder.—2. The Dimension of the Circle, or proportion between the diameter and the circumference.—3. Of Spiral lines.—4. Of Conoids and Spheroids.—5. Of Equipoindants, or Centres of Gravity.—6. The Quadrature of the Parabola.—7. Of Bodies floating on Fluids.—8. Lemmata.—9. Of the Number of the Sands.

Among the works of Archimedes which are lost, may be reckoned the descriptions of the following inventions, which may be gathered from himself and other ancient authors. 1. His account of the method which he employed to discover the mixture of gold and silver in the crown, mentioned by Vitruvius.—2. His description of the Cochleon, or engine to draw water out of places where it is stagnated, still in use under the name of Archimedes's Screw. Athenaeus, speaking of the prodigious ship built by the order of Hiero, says, that Archimedes invented the cochleon, by means of which the hold, notwithstanding its depth, could be drained by one man. And Diiodorus Siculus says, that he contrived this machine to drain Egypt, and that by a wonderful mechanism it would exhaust the water from any depth.—3. The Helix, by means of which, Athenaeus informs us, he launched Hiero's great ship.—4. The Trispaston, which, according to Tzetzes and Origen, could draw the most stupendous weights.—5. The machines, which, according to Polybius, Livy, and Plutarch, he used in the defence of Syracuse against Marcellus, consisting of Tormenta, Ballistæ, Catapults, Sagittarii, Scorpions, Cranes, &c.—6. His Burning Glasses, with which he set fire to the Roman galleys.—7. His Pneumatic and Hydrostatic engines, concerning which subjects he wrote some books, according to Tzetzes, Pappus, and Tertullian.—8. His Sphere, which exhibited the celestial motions. And probably many others.

A whole volume might be written on the curious methods and inventions of Archimedes, that appear in his mathematical writings now extant only. He was the first who squared a curvilinear space; unless Hypocrates must be excepted, on account of his lunes. In his time the conic sections were admitted into geometry, and he applied himself closely to the measuring of them, as well as other figures. Accordingly, he determined the relations of spheres, spheroids, and conoids, to cylinders and cones; and the relations of parabolas to rectilineal planes, whose quadratures had long before been determined by Euclid. He has left us also his attempts upon the circle: he proved that a circle is equal to a right-angled triangle, whose base is equal to the circumference, and its altitude equal to the radius; and consequently, that its area is equal to the rectangle of half the diameter and half the circumference; thus reducing the quadrature of the circle to the determination of the ratio between the diameter and circumference; which determination however has never yet been done. Being disappointed of the exact quadrature of the circle, for want of the rectification of its circumference, which all his methods would not effect, he proceeded to assign a useful approximation to it: this he effected by the numerical calculation of the perimeters of the inscribed and circumscribed polygons; from which calculation it appears, that the perimeter of the circumscribed regular polygon of 192 sides, is to the diameter, in a less ratio than that of $3\frac{1}{7}$ or $3\frac{5}{8}$ to 1; and that the perimeter of the inscribed polygon of 96 sides, is to the diameter, in a greater ratio than that of $3\frac{7}{9}$ to 1; consequently, that the ratio of the circumference to the diameter, lies between these two ratios. Now the first ratio, of $3\frac{1}{7}$ to 1, reduced to whole numbers, gives that of 22 to 7, for $3\frac{1}{7} : 1 : : 22 : 7$; which therefore is nearly the ratio of the circumference to the diameter. From this ratio between the circumference and the diameter, Archimedes computed the approximate area of the circle, and he found that it is to the square of the diameter, as 11 is to 14.

He determined also the relation between the circle and the ellipse, with that of their similar parts. And it is probable that he also attempted the hyperbola; but it is not to be expected that he met with any success, since approximations to its area are all that can be given by the various methods that have since been invented.

Besides these figures, he determined the measures of the spiral, described by a point moving uniformly along a right line, the line at the same time revolving with a uniform angular motion; determining the proportion of its area to that of the circumscribed circle, as also the proportion of their sectors.

Throughout the whole works of this great man we every where perceive the deepest design, and the finest invention. He seems to have been, with Euclid, exceedingly careful of admitting into his demonstrations nothing but principles perfectly geometrical and unexceptionable: and though his most general method of demonstrating the relations of curved figures to straight ones, be by inscribing polygons in them; yet to determine those relations, he does not increase the number, and diminish the magnitude, of the sides of the polygon *ad infinitum*, but from this plain fundamental principle, allowed in Euclid's Elements, (viz, that any quantity may be so often multiplied, or added to itself, as that the result shall exceed any proposed finite quantity of the same kind,) he proves that to deny his figures to have the proposed relations, would involve an absurdity. And when he demonstrated many geometrical properties, particularly in the parabola, by means of certain progressions of numbers, whose terms are similar to the inscribed figures; this was still done without considering such series as continued *ad infinitum*, and then collecting or summing up the terms of such infinite series.

There have been various editions of the existing writings of Archimedes. The whole of these works, together with the Commentary of Eutocius, were found in their original Greek language, on the taking of Constantinople, whence they were brought into Italy; and here they were found by that excellent mathematician John Muller, otherwise called Regiomontanus, who brought them into Germany: where they were, with that Commentary, published long afterwards, viz, in 1544, at Basil, being most beautifully printed in folio, both in Greek and Latin, by Hervagius, under the care of Thomas Gechauff Venatorius.—A Latin translation was published at Paris 1557, by Pascalias Hamellius.—Another edition of the whole, in Greek and Latin, was published at Paris 1615, in folio, by David Rivaltus, illustrated with new demonstrations and commentaries: a life of the author is prefixed; and at the end of the volume is added some account, by way of restoration, of our author's other works, which have been lost; viz, The Crown of Hiero; the Cochleon or Water Screw; the Helicon, a kind of endless screw; the Trispaston, consisting of a combination of wheels and axles; the Machines employed in the defence of Syracuse; the Burning Speculum; the Machines moved by Air and Water; and the Material Sphere.—In 1675, Dr. Isaac Barrow published a neat edition of the works, in Latin, at London, in 4to; illustrated, and succinctly demonstrated in a new method.—But the most complete of any, is the magnificent edition, in folio, lately printed at the Clarendon press, Oxford, 1792. This edition was prepared ready for the press by the learned Joseph Torelli, of Verona, with his preface, and in that state presented to

the University of Oxford. The Latin translation is a new one. We find here also Eutocius's Commentary on some of the pieces, and notes on the whole. An account of the life and writings of Torelli is prefixed, by Clemens Sibillati. And at the end a large appendix is added, in two parts; the first being a *Commentary on Archimedes's paper on Bodies that float on Fluids*, by the Rev. Abram Robertson of Christ-Church College, who had the care of this edition; and the latter is a large collection of various readings in the manuscript works of Archimedes, found in the library of the late king of France, and of another at Florence, as collated with the Basil edition above mentioned.

There are al-o extant other editions of certain parts of the works of Archimedes. Thus, Commandine published, in 4to, at Bologna 1565, the two books concerning Bodies that float on Fluids, with a *Commentary*. Commandine published also a translation of the *Arenarius*. And Borelli published, in folio, at Florence, 1661, Archimedes's *Liber Assumptorum*, translated into Latin from an Arabic manuscript copy. This is accompanied with the like translation, from the Arabic, of the 5th, 6th, and 7th books of Apollonius's *Conics*. Mr. G. Anderson published (in 8vo. Lond. 1784) an English translation of the *Arenarius* of Archimedes, with learned and ingenious notes and illustrations. Dr. Wallis published a translation of the *Arenarius*. Lastly, the translation of Torelli's work into the French language, by F. Peyrard, in 2 vols. 8vo, at Paris, in 18—, and 1808. And there may be other editions beside the above; but these are all that I have seen, or know of.

Archimedes's Screw. See *Screw of Archimedes*.

Archimedes's Burning-glass. See *Burning-glass*.

ARCHITECT, a person skilled in architecture, or the art of building; who forms plans and designs for edifices, conducts the work, and directs the various artificers employed in it.

The most celebrated architects are, Vitruvius, Palladio, Scamozzi, Serlio, Vignola, Barbaro, Cataneo, Alberti, Viola, Inigo Jones, De Lorme, Perrault, S. Le Clerc, Sir Christopher Wren, the Earl of Burlington, &c.

ARCHITECTURE, *Architectura*, the art of planning and building or erecting any edifice, so as properly to answer the end proposed, for solidity, conveniency, and beauty; whether houses, temples, churches, bridges, halls, theatres, &c., &c.—Architecture is divided into civil, military, and naval or marine.

Civil Architecture, is the art of designing and erecting edifices of every kind for the uses of civil life in every capacity; as churches, palaces, private houses, &c.; and it has been divided into five orders or manners of building, under the names of the Tuscan, Doric, Ionic, Corinthian, and Composite.

There were many authors on architecture among the Greeks and Romans, before Vitruvius; but he is the first whose work is entire and extant. He lived in the reigns of Julius Caesar and Augustus, and composed a complete system of architecture, in ten books, which he dedicated to this prince. The principal authors on architecture since Vitruvius, are Philander, Barbarus, Salmasius, Baldus, Alberti, Gauricus, Demonius, Perrault, De l'Orme, Rivius, Wotton, Serlio, Palladio, Strada, Vignola, Scamozzi, Dicussart, Catanei, Freard, De Cambrai, Blondel, Goldman, Sturmy, Wolfius, De Rosi, Desgodetz, Baratteri, Mayer, Gulielmus, Ware, &c., &c. See also *ARCHITECT*.

Military Architecture, otherwise more usually called

Fortification, is the art of strengthening and fortifying places, to secure them from the insults or attacks of enemies, and the violence of arms; by erecting forts, castles, and other fortresses, with ramparts, bastions, &c.—The authors who have chiefly excelled in this art, are Cochon, Pagan, Vauban, Scheiter, Blondel, and Montalembert.

Naval ARCHITECTURE, or *Ship-building*, is the art of constructing ships, galleys, and other vessels proper to float on the water.

ARCHITRAVE, is that part of a column which bears immediately on the capital. It is the lowest member of the entablature, and is supposed to represent the principal beam in timber buildings, in which it is sometimes called the Reason-piece, or Master-piece. Also, in chimneys it is called the Mantle-piece; and the Hyperthyron over the jaumbs of doors, or lintels of windows.

Architrave Cornice. See *CORNICE*.

ARCHITRAVE doors, are those which have an architrave on the jaumb, and over the door; on the cap piece if straight; or on the arch, if the top be curved.

ARCHITRAVE windows, of timber, are usually an ogee raised out of the solid timber, with a list over it: though sometimes the mouldings are struck, and laid on; and sometimes they are cut in brick.

ARCHIVault or ARCHIVolt, the contour of an arch; a band or frame adorned with mouldings, running over the faces of the voussoirs or arch-stones, and bearing upon the imposts.

ARCYTAS, of Tarentum, a celebrated mathematician, cosmographer, and Pythagorean philosopher, whom Horace calls

— Maris ac Terræ, numeroque parentis Arena,
Mensem.

He flourished about 400 years before Christ; and was the master of Plato, Eudoxus, and Philolaus. He gave a method of finding two mean proportionals between two given lines, and thence the duplication of the cube, by means of the conic sections. His skill in mechanics was such, that he was said to be the inventor of the crane and the screw; and he made a wooden pigeon that could fly about, when it was once set off, but it could not rise again of itself, after it rested. He wrote several works, though none of them are now extant, particularly a treatise *περ τὸν Ιανόν*, *De Universo*, cited by Simplicius in Aristot. Categ. It is said he invented the ten categories. He acquired great reputation both in his legislative and military capacity; having commanded an army seven times without ever being defeated. He was at last shipwrecked, and drowned in the Adriatic sea.

ARCTIC Circle, is a lesser circle of the sphere, parallel to the equator, and passing through the north pole of the ecliptic, or distant from the north or arctic pole, by a quantity equal to the obliquity of the ecliptic, which was formerly estimated at $23^{\circ} 30'$, but its mean quantity is now $23^{\circ} 28'$ nearly. This, and its opposite, the antarctic circle, are also called the polar circles, where the longest day and longest night are 24 hours, and within all the space of these circles, at one time of the year, the sun never sets, and at the opposite season he never rises for some days, more or less according as the place is nearer the pole.

ARCTIC Pole, the north pole of the world, and so called from *άρκτος, ursa*, the bear, from its proximity to the constellation of that name.

ARCTURUS, a fixed star of the first magnitude, between the thighs, of the constellation Bootes. So called

from ἄρκτος, bear, and ῥάριον, tail; as being near the bear's tail. This star is twice mentioned in the book of Job, viz, ix. 9, and xxxviii. 32, by the name Aish, if the translation be right; and by many of the ancients under its Greek name *Arcturus*. The Greeks gave the fabulous history of this star, or constellation, to this purport: Calisto, who was afterwards, in form of the great bear, raised up into a constellation, they tell us, brought forth a son to Jupiter, whom they called Arcas. That Lyacon, when Jupiter afterwards came to visit him, cut the boy in pieces, and served him up at table. Jupiter, in revenge, as well as by way of punishment, called down lightning to consume the palace, and turned the monarch into a wolf. The limbs of the boy were gathered up, to which the god gave life again, and he was taken and educated by some of the people. His mother, who was all this time a bear in the woods, fell in his way: he chased her, ignorant of the fact, and, to avoid him, she threw herself into the temple of Jupiter: he followed her thither to destroy her; and this being death by the laws of the country, Jupiter took them both up into heaven, to prevent the punishment, making her the constellation of the great bear, and converting the youth into this single star behind her.

Dr. Hornsby, the Savilian Professor of Astronomy, concludes that Arcturus is the nearest star to our system visible in the northern hemisphere, because the variation of its place, in consequence of a proper motion of its own, is more remarkable than that of any other of the stars; and by comparing a variety of observations respecting both the quantity and direction of the motion of this star, he infers, that the obliquity of the ecliptic decreases at the rate of $55''$ in 100 years; a quantity which nearly corresponds to the mean of the computations framed by Euler, La Lande, and Laplace, on the principles of attraction. Philos. Trans. vol. 63.

AREA, in general, denotes any plain surface to walk upon; and derived from *arere*, to be dry.

AREA, in Architecture, denotes the space or site of ground on which an edifice stands. It is also used for inner courts, and such like portions of ground.

AREA, in Geometry, denotes the superficial content of any figure. The areas of figures are estimated in squares and parts of squares. Thus, suppose a rectangle *EFGH* have its length *EH* equal to 4 inches, or feet, or yards, &c, and its breadth *EF* equal to 3; its area will then be 3 times 4, or 12 squares, each side of which is respectively one inch, or foot, or yard, &c. The areas of other particular figures may be seen under their respective names.

The areas of all similar figures, are in the duplicate ratio, or as the squares of their like sides, or of any like linear dimensions.—Also the law by which the planets move round the sun, is regulated by the areas described by a line connecting the sun and planet; that is, the time in which the planet describes, or passes over, any arc of its elliptic orbit, is proportional to the elliptic area described in that time by the said line, or the sector contained by the said arc and two radii drawn from its extremes to the focus in which the sun is placed.

AREA, in Optics. See *FIELD*.

ARENARIUS, the name of a book of Archimedes, in which he demonstrated, that not only the sands of the earth, but even a greater quantity of particles than could

be contained in the immense sphere of the fixed stars, might be expressed by numbers, in a way by him invented and described. This notation proceeds by certain geometrical progressions; and in denoting and producing certain very distant terms of the progression, he here first of any one makes use of a property similar to that of logarithms, viz, adding the indices of the terms to find the index of their product. See *ARCHIMEDES*.

AREOMETER, *AREOMETRUM*, an instrument to measure the density or gravity of water.

The areometer, or water-poise, is commonly made of glass; consisting of a round hollow ball, which terminates in a long slender neck, hermetically sealed at top; having first as much running mercury put into it, as will serve to balance or keep it swimming in an erect position. The stem, or neck, is divided into degrees or parts, which are numbered, to show, by the depth of its descent into any liquor, the lightness or density of it: for that fluid is heaviest in which it sinks least, and lightest in which it sinks deepest.

Another instrument of this kind is described by Homberg of Paris, in the Memoirs of the Acad. of Sciences for the year 1699; also in the Philos. Trans. N° 262, where a table of numbers is given, expressing the density of various fluids, as determined by this instrument both in summer and winter. By this table it appears that the density, or specific gravity of quicksilver and distilled water, in the two seasons, were as follow, viz,

in summer as	-	-	13·61 to 1,
in winter as	-	-	13·53 to 1;

and the medium of these two is as 13·57 to 1.

See the Philos. Trans. vol. 36; or my *Abridg.* vol. 7, for the description and use of another new areometer. See also *HYDROMETER*.

AREOMETRY, the science of measuring the gravity and density of fluids. See the Philos. Trans. vol. 63, for an essay on areometry, &c. Also my *Abridgement*, vol. 14.

AREOSTYLE, in Architecture, a sort of intercolumniation in which the columns were placed at a great distance from one another.

ARGETENAR, a star of the fourth-magnitude, in the flexure of the constellation *Eridanus*.

ARGO NAVIS, or the ship, is a constellation of fixed stars, in the southern hemisphere, being one of the 48 old constellations. The number of stars in this constellation, are, in Ptolemy's catalogue 45, in Tycho Brahe's 11, in Flamsteed's 64.

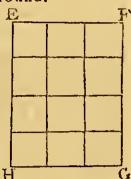

The Greeks tell us, that this was the noted ship in which the Argonauts performed that celebrated expedition, which has been so famous in all their history.

ARGUMENT, in Astronomy, is an arch given, by which another arch is found in some proportion to it. Hence,

ARGUMENT OF INCLINATION, or **ARGUMENT OF LATITUDE**, of any planet, is an arc of a planet's orbit, intercepted between the ascending node, and the place of the planet from the sun, numbered according to the succession of the signs.

Menstrual ARGUMENT of Latitude, is the distance of the moon's true place from the sun's true place.—By this is found the quantity of the real obscuration in eclipses, or how many digits are darkened in any place.

Annual ARGUMENT of the moon's apogee, or simply, **Annual Argument**, is the distance of the sun's place from the place of the moon's apogee; that is, the arc of the elliptic comprised between those two places.

ARIES, or the *Ram*, in Astronomy, one of the constellations of the northern hemisphere, being the first of the old twelve signs of the zodiac, and marked φ in imitation of a ram's head. It gives name to a twelfth part of the ecliptic, which the sun enters commonly about the 20th of March.—The stars of this constellation in Ptolemy's catalogue are 18, in Tycho Brahe's 21; in Hevelius's 27, and in Flamsteed's 66: but they are mostly very small, only one being of the 2d magnitude, two of the 3d magnitude, and all the rest smaller.

The fabulous account of this constellation, as given by the Greeks, is to this effect. That Nephele gave Phryxus, her son, a ram, which bore a golden fleece, as a guard against the greatest dangers. Juno, the step-mother both of him and Helle, laid designs against their lives; but Phryxus, remembering the admonition of his mother, took his sister with him, and getting upon the back of the ram, they were carried to the sea. The ram plunged in, and the youth was carried over; but Helle dropping off, was drowned, and so gave name to the Hellespont. When he arrived in Colchis, Δ æta the king received him kindly; and, sacrificing the ram to Jupiter, dedicated the fleece to the god; which was afterwards carried off by Jason. The animal itself, they say, Jupiter snatched up into the heavens, and made of it the constellation Aries. They have other fables also to account for its origin. But it is most probable that the inventors of this sign, placed it there as the father of those animals which are brought forth about the time the sun approaches to that part of the heavens, and so marking the beginning of spring.

ARIES also denotes a battering ram; being a military engine with an iron head, much used by the ancients, to batter and beat down the walls of places besieged. See RAM, and BATTERING Ram.

ARISTARCHUS, a celebrated Greek philosopher and astronomer, was a native of the city of Samos; but of what date is not exactly known; it must have been however before the time of Archimedes, as some parts of his writings and opinions are cited by that author, viz, in his Arenarius; he probably flourished about 420 years before Christ. He held the opinion of Pythagoras as to the system of the world, but whether before or after him, is uncertain, teaching that the sun and stars were fixed in the heavens, and that the earth moved in a circle about the sun, at the same time that it revolved about its own centre or axis. He taught also, that the annual orbit of the earth, compared with the distance of the fixed stars, is but as a point. On this head Archimedes says, "Aristarchus, the Samian, confuting the notions of astrologers, laid down certain positions, from which it follows, that the world is much larger than is generally imagined; for he lays it down, that the fixed stars and the sun are immovable; and that the earth is carried round the sun in the circumference of a circle. On which account, though he might not suffer persecution and imprisonment like Galileo, yet he did not escape censure for his supposed impiety; for it is said Cleanthus was of opinion, that Greece ought to have tried Aristarchus for irreligion, for endeavouring to preserve the regular appearance of the heavenly bodies, by supposing that the heavens themselves stood still; but that the earth revolved in an oblique circle, and at the same time turned round its own axis."

Aristarchus invented a peculiar kind of sun-dials, mentioned by Vitruvius. There is extant of his works only a treatise on the magnitude and distance of the sun and

moon: this was translated into Latin, and commented on by Commandine, who first published it with Pappus's Explanations, in 1572. Dr. Wallis afterwards published it in Greek, with Commandine's Latin version, in 1688, and which he inserted again in the 3d volume of his Mathematical Works, printed in folio at Oxford, 1699. The piece was animadverted on by Mr. Foster, in his Miscellanies. There is another piece which has gone under the name of Aristarchus, on the Mundane System, its parts, and motions, published in Latin by Roberval, and by Mersenne, in his Mathematical Synopsis. But this piece is censured, by Menagius (in Diog. Laert.), and Descartes, in his Epistles, as a fictitious piece of Roberval's, and not the genuine work of Aristarchus.

ARISTOTELIAN, something that relates to the philosopher Aristotle. Thus we say, an Aristotelian dogma, the Aristotelian school, &c.

ARISTOTELIAN Philosophy, the philosophy taught by Aristotle, and maintained by his followers. It is otherwise called the Peripatetic Philosophy, from their practice of teaching while they were walking.—The principles of Aristotle's philosophy, the learned agree, are chiefly laid down in the four books de Cœlo. Instead of the more ancient systems, he introduced Matter, Form, and Privation, as the principles of all things; but it does not seem that he derived much benefit from them in natural philosophy. And his doctrines are, for the most part, so obscurely expressed, that it has not yet been satisfactorily ascertained, what were his sentiments on some of the most important subjects. He attempted to refute the Pythagorean doctrine concerning the two-fold motion of the earth; and pretended to demonstrate, that the matter of the heavens is ungenerated, incorruptible, and not subject to any alteration: and he supposed that the stars were carried round the earth in solid orbs.

ARISTOTELIANS, a sect of philosophers, so called, from their leader Aristotle, and are otherwise called Peripatetics.—The Aristotelians and their dogmata prevailed for a long while, in the schools and universities; even in spite of all the efforts of the Cartesians, Newtonians, and other corpuscularians. But the systems of the latter have at length gained the ascendency; and the Newtonian philosophy in particular is now very generally received.

ARISTOTLE, a Grecian philosopher, the son of Nicomachus, physician to Amyntas king of Macedonia, was born 384 years before Christ, at Stagira, a town of Macedonia, or, as others say, of Thrace; from which he is also called the Stagirite. Not succeeding in the profession of arms, to which it seems he first applied himself, he turned his views to philosophy, and at 17 years of age entered himself a disciple of Plato, and attended in the academy till the death of that philosopher. Aristotle then retired to Atarna, where the prince Hermias gave him his daughter to wife. Repairing afterwards to the court of king Philip, he became preceptor to his son, Alexander the Great, whose education he attended for the space of 8 years; and by the magnificent encouragement of this prince he was afterwards enabled to procure all sorts of animals, from the inspection of which to write their history. On his quitting Macedon, he settled at Athens, where he established his school, having the Lyceum assigned him, by the magistrates, for the place of his instruction or disputation; where he became the head and founder of the sect called after his name, as also Peripatetics, from the circumstance of his giving instructions

while walking. But being here accused of impiety by Eurymedon, priest of Ceres, and fearing the fate of Socrates, he retired to Chalcis, where he died at 63 years of age, and 322 years before Christ. Some say that he poisoned himself, others that he died of a colic, and others again pretend that he threw himself into the sea, for grief that he could not discover the cause of the flux and reflux of the waters. Laertius, in his life of Aristotle, estimates his books at the number of 4000; of which however scarce 20 have come down to us: these may be comprised under five heads; the first, relating to poetry and rhetoric; the second, to logics; the third, to ethics and polities; the fourth, to physics; and the fifth, to metaphysics. In the schools, Aristotle has been called the philosopher, and the prince of philosophers. Indeed, such was the veneration paid to him, that his opinion was allowed to stand on a level with reason itself: nor was any appeal from it admitted, the parties, in every dispute, being obliged to show, that their conclusions were no less conformable to the doctrine of Aristotle than to truth.

Aristotle's Mechanics were published in Greek and Latin, at Paris, in 4to, 1599, by Henry Monanthol, physician, and royal professor of the Mathematical arts, with a large commentary in Latin. This is a very short tract, and consists chiefly in explaining the reasons or causes of certain motions, and machines, and natural effects; some being true, and others erroneous. In explaining many physical phenomena, he takes occasion to advert to the properties of the simple mechanical powers, the lever, the balance, the statera, the wheel-and-axle, the wedge, the screw, and the pulley; of which, most or all, he observes, may be referred to the lever, by means of which most mechanical effects are produced.—The form of the work, is by way of answering certain queries, and explaining natural effects, and seeming contraries or paradoxes: as,

1. Of a circular line which, without any breadth, has both convexity and concavity.

2. How two things, the one moving the other, may move contrary ways at the same time; as when one wheel turns another, by means of teeth on their circumferences, while the one turns from right to left, the other turns from left to right.

3. In a balance, because a greater line revolves circularly quicker than a less, therefore the larger balances are more exact than the smaller.

4. That two lines moved parallelwise, in different directions, with velocities having always the same ratio, have their intersection always in the diameter or diagonal of the parallelogram having its sides in the directions of the motions. Or, one line moved parallelwise, while a point moves along the line, with a motion in a constant ratio to that of the line; the point moves always in the diagonal of the said parallelogram. And this is the same as the celebrated theorem of the parallelogram of motions, or of forces. But if the motions be not always in the same ratio, then the intersections will not be in the diagonal of a parallelogram.

5. On the variable motions, to cause the intersections to describe the periphery of a circle.

6. On the affections and properties of scales or balances.

7. On the cause of the power of the lever.—That the weight and power are reciprocally proportional to the arms of the lever.

8. Hence the reason why the oars are the most efficacious

of those rowers who are seated in the middle of the ship.

9. On the cause of the power of the rudder, in turning the ship.

10. On the cause of the power of the sail-yard in a ship. As the yard is placed higher up, on the mast, so much quicker will the ship be moved, with the same wind and the same sail; because the lever (or distance up the mast) is so much the longer.

11. On shifting the sails and rudder when turning the corners and windings of a river.

12. Why round or circular figures are more moveable.

13. Why the greatest circles are the most moveable.

14. Why balista without weight are more easily moved.

15. Why a heavy or loaded carriage is easier than a light or running one.

16. Why stone is thrown farther from a sling, than when thrown by the hand.

17. On the wheel-and-axle, and tooth-and-pinion work.

18. On the breaking of wood. Why a stick is more easily broken over the knee, when the extremities are held by the hands, than when held nearer the middle.

19. On the roundness of pebbles, or why those about the sea-shore are round; viz, from the continual rolling by the motion of the waters.

20. Why wood is weaker as it is longer.

21. The cause of the power of the wedge, is chiefly owing to percussion.

22. Of the pulley or little wheel.

23. Why an ax by striking divides; but by pressing not: because in the former way it acts as a thin wedge.

24. Of the Statera, or Steelyard.

25. Of the Dentiducio, or Toothdrawer.

26. Of the Nutcracker.

27. Why, in a Rhombus, both the extreme points do not describe or pass over equal right lines. That is, either extreme point moving along an adjacent side, while that side is carried by an equal parallel motion, then the point describes the adjacent diagonal of the rhombus. But the diagonal connecting the acute angles of the rhombus, being greater than the other which connect the obtuse angular points; therefore the motion of the acute angular point, is so much greater than that of the other.

28. Why a greater circle revolves equally with a less, when posited about the same centre.

29. Of Beds.—Why the sides of a bed are made in a double ratio; the one being 6 feet, or little more; the other only 3. And why the cordings are not extended diagonally. Or that they be made in such magnitude as to correspond with the bodies. For thus the sides will be double, as 4 cubits in length, and 2 in breadth.

30. Why it is more difficult to support a long stick at the extremity of the arm, than in the middle of it.

31. Why it is more difficult to support, at the extremity of the arm, a very long weight, than a short one.

32. Why a tullenio for drawing water, acts better as it works with a heavy weight at the end of the cross bar.

33. Why, when two men carry a weight on a pole between them, they are not equally pressed when it is not in the middle between them.

34. Why those who rise up from a seat, put themselves into a particular position; viz, putting their feet backwards, and bending their body forward.

35. Why a moving body is more easily moved, than a quiescent one.

36. Why a lath or rod projected loses of its motion.—This, and the former cause, Aristotle seems not to understand.

37. Why any thing proceeds not on in the direction of its motion, but relaxes, when impelled in the contrary direction. As, when its weight causing it to descend downwards, is greater than the impulsive force can impel it upwards.

38. Why any things, either small or large, when projected, do not go far.

39. Why a light body, floating in a vortex of water, goes into the middle of the vortex.

ARITHMETIC, is the art and science of numbers; or, that part of mathematics which considers their powers and properties, and teaches how to compute or calculate truly, with ease and expedition. It is by some authors also defined the science of discrete quantity. Arithmetic consists chiefly in the four principal rules or operations of Addition, Subtraction, Multiplication, and Division; to which may perhaps be added involution and evolution, or raising of powers and extraction of roots. But besides these, for the facilitating and expediting of computations, mercantile, astronomical, &c, many other useful rules have been contrived, which are applications of the former, such as, the rules of proportion, progression, alligation, false position, fellowship, interest, barter, rebate, equation of payments, reduction, tare and tret, &c; besides the doctrine of the curious and abstract properties of numbers.

Very little is known of the origin and invention of arithmetic. In fact it must have commenced with mankind, or as soon as they began to hold any sort of commerce together; and must have undergone continual improvements, as occasion was given by the extension of commerce, and by the discovery and cultivation of other sciences. It is therefore very probable that the art has been greatly indebted to the Phœnicians or Tyrians; and indeed Proclus, in his commentary on the first book of Euclid, says, that the Phœnicians, by reason of their traffic and commerce, were accounted the first inventors of Arithmetic. From Asia the art passed into Egypt, whither it was carried by Abraham, according to the opinion of Josephus. Here it was greatly cultivated and improved; insomuch that a considerable part of the Egyptian philosophy and theology seems to have turned altogether upon numbers. Hence those wonders related by them about unity, trinity, with the numbers 4, 7, 9, &c. In effect, Kircher, in his Oedip. Egypt. shows, that the Egyptians explained every thing by numbers; Pythagoras himself affirming, that the nature of numbers pervades the whole universe; and that the knowledge of numbers is the knowledge of the Deity.

From Egypt arithmetic was transmitted to the Greeks, by means of Pythagoras and other travellers; among whom it was greatly cultivated and improved, as appears by the writings of Euclid, Archimedes, and others: with these improvements it passed to the Romans, and from them it has descended to us.

The nature of the arithmetic however that is now in use, is very different from that above alluded to; this art having undergone a total alteration by the introduction of the Arabic or Indian notation, about 8 or 9 hundred years since, into Europe: so that nothing now remains of use from the Greeks, but the theory and abstract properties of numbers, which have no dependence on the peculiar nature of any particular scale or mode of notation. That

used by the Hebrews, Greeks, and Romans, was chiefly by means of the letters of their alphabets. The Greeks, particularly, had two different methods; the first of these was much the same with the Roman notation, which is sufficiently well known, being still in common use with us, to denote dates, chapters and sections of books, &c. Afterwards they had a better method, in which the first nine letters of their alphabet represented the first numbers, from one to nine, and the next nine letters represented any number of tens, from one to nine, that is, 10, 20, 30, &c, to 90. Any number of hundreds they expressed by other letters, supplying what they wanted with some other marks or characters: and in this order they went on, using the same letters again, with some different marks, to express thousands, tens of thousands, hundreds of thousands, &c: in which it is evident that they approached very near to the more perfect decuple scale of progression used by the Arabians, and who acknowledge that they had received it from the Indians. Archimedes also invented another peculiar scale and notation of his own, which he employed in his Arenarius, to compute the number of the sands. Ptolemy is supposed to have invented the sexagesimal division of numbers, with its peculiar notation and operations: a mode of computation still used in astronomy, &c, for the subdivisions of the degrees of circles. Those notations however were ill adapted to the practical operations of arithmetic: and hence it is that the art advanced but very little in this part; for, setting aside Euclid, who has given many plain and useful properties of numbers in his Elements, and Archimedes, in his Arenarius, they mostly consist in dry and tedious distinctions and divisions of numbers; as appears from the treatises of Nicomachus, supposed to be written in the 3d century of Rome, and published at Paris in 1538; as also that of Boethius, written at Rome in the 6th century. A compendium of the ancient arithmetic, written in Greek, by Psellus, in the 9th century, was published in Latin by Xylander, in 1536. A similar work was written soon after in Greek by Joducus Willichius; and a more ample work of the same kind was written by Jordanus, in the year 1200, and published with a comment by Faber Stapulensis in 1480.

Since the introduction of the Indian notation into Europe, about the 10th century, arithmetic has greatly changed its form, the whole algorithm, or practical operations with numbers, being quite altered, as the notation required; and the authors of arithmetic have gradually become more and more numerous. This method was brought into Spain by the Moors or Saracens; whither the learned men from all parts of Europe repaired, to learn the arts and sciences of them. This, Dr. Wallis proves, began about the year 1000; particularly that one Gerbert, a monk, afterwards pope Sylvester the 2nd, who died in the year 1003, brought this art from Spain into France, long before the date of his death: and that it was known in Britain before the year 1150, where it was brought into common use before 1250, as appears by the treatise of arithmetic of Johannes de Sacro Bosco, or Halifax, who died about 1256. Since that time, the principal writers on this art have been, Barlaam, Lucas de Burgo, Tonstall, Aventinus, Purbach, Cardan, Scheubelius, Tartalia, Fafer, Stifelius, Regius, Recorde, Ramus, Maurolycus, Hemischius, Peletarius, Stevinus, Xylander, Kersey, Snellius, Tacquet, Clavius, Metius, Gemma Frisius, Buteo, Ursinus, Romanus, Napier, Ceulen, Wingate, Kepler, Briggs, Ulacq, Oughtred, Cruger, Van Schooten, Wallis, Dec, Newton,

Morland, Moore, Jeake, Ward, Hatton, Malcolm, &c, &c; the particular inventions or excellencies of whom, will be noticed under the articles of the several species or kinds of arithmetic here following, which may be included under these heads, viz, Theoretical, Practical, Instrumental, Logarithmical, Numerous, Specious, Universal, Common or Decadal, Fractional, Radical or of Surds, Decimal, Duodecimal, Sexagesimal, Dynamical or Binary, Tetractycal, Political, &c.

Theoretical ARITHMETIC, is the science of the properties, relations, &c, of numbers, abstractedly considered; with the reasons and demonstrations of the several rules. Such is that contained in the 7th, 8th, and 9th books of Euclid's Elements; the Logistics of Barlaam the monk, published in Latin by J. Chambers, in 1600; the Summa Arithmetica of Lucas de Burgo, printed 1494, who gives the several divisions of numbers from Nicomachus, and their properties from Euclid, with the algorithm, both in integers, fractions, extraction of roots, &c; Malcolm's New System of Arithmetic, Theoretical and Practical, in 1730, in which the subject is very completely treated, in all its branches, &c.

Practical ARITHMETIC, is the art or practice of numbering or computing; that is, from certain numbers given, to find others which shall have any proposed relation to the former. As, having the two numbers 4 and 6 given; to find their sum, which is 10; or their difference, which is 2; or their product, 24; or their quotient, $1\frac{1}{2}$; or a third proportional to them, which is 9; &c.—Lucas de Burgo's works contain the whole practice of arithmetic, then used, as well as the theory. Tunstall gave a neat practical treatise of Arithmetic in 1526; as did Stifelius, in 1544, both on the practical and other parts. Tartalea gave an entire body of practical arithmetic, which was printed at Venice in 1556, consisting of two parts; the former, the application of arithmetic to civil uses; the latter, the grounds of algebra. And most of the authors in the list before enumerated, joined the practice of arithmetic with the theory.

Binary or Dyadic ARITHMETIC, is that in which only two figures are used, viz, 1 and 0. See **BINARY.**—Leibnitz and De Lagny both invented an arithmetic of this sort, about the same time: and Dangicourt, in the Miscel. Berol. gives a specimen of the use of it in arithmetical progressions; where he shows, that the laws of progression may be more easily discovered by it, than by any other method where more characters are used.

Common or Vulgar ARITHMETIC, is that which is concerning integers and vulgar fractions.

Decimal or Decadal ARITHMETIC, is that which is performed by a series of ten characters or figures, the progression being ten-fold, or from 1 to 10's, 100's, &c; which includes both integers and decimal fractions, in the common scale of numbers; and the characters used are the ten Arabic or Indian figures 0, 1, 2, 3, 4, 5, 6, 7, 8, 9. This method of arithmetic was not known to the Greeks and Romans; but was borrowed from the Moors while they possessed a great part of Spain, and who acknowledge that it came to them from the Indians. It is probable that this method took its origin from the ten fingers of the hands, which were used in computations before arithmetic was brought into an art. The Eastern missionaries assure us, that to this day the Indians are very expert at computing on their fingers, without any use of pen and ink. And it is asserted, that the Peruvians, who perform all computations by the different arrangements of grains of maize, per-

outdo any European, both for certainty and dispatch, with all his rules.

Duodecimal ARITHMETIC, is that which proceeds from 12 to 12, or by a continual subdivision according to 12. This is greatly used by most artificers, in squaring or calculating the quantity of their work; as Bricklayers, Carpenters, Painters, Tilers, &c.

Fractional ARITHMETIC, or of fractions, is that which treats of fractions, both vulgar and decimal.

Harmonical ARITHMETIC, is so much of the doctrine of numbers, as relates to making the comparisons, reductions, &c, of musical intervals.

ARITHMETIC OF INFINITES, is the method of summing up a series of numbers, of which the number of terms is infinite. This method was first invented by Dr. Wallis, as appears by his treatise on that subject; where he shows its uses in geometry, in finding the areas of superficies, the contents of solids, &c. But the method of fluxions, which is a kind of universal arithmetic of infinites, performs all these more easily; as well as a great many other things, which the former cannot reach.

Instrumental ARITHMETIC, is that in which the common rules are performed by instruments, or some sort of tangible or palpable substance. Such are the methods of computing by the ten fingers and the grains of maize, by the East-Indians and Peruvians, above-mentioned; by the Abacus or Shwanpan of the Chinese; the several sorts of scales and sliding rules; Napier's bones or rods; the arithmetical machine of Pascal, and others; Sir Samuel Morland's instrument, described in 1666; that of Leibnitz, described in the MisCELL. Berol.; that of Polenus, published in the Venetian Miscellany, 1709; and that of Dr. Saunderson, of Cambridge, described in the introduction to his Algebra.

Integral ARITHMETIC, or of integers, is that which respects integers, or whole numbers.

LITERAL ARITHMETIC, or Algebra, is that which is performed by letters, which represent any numbers indefinitely.

LOGARITHMICAL ARITHMETIC is performed by the tables of logarithms. These were invented by baron Napier; and the best treatise on the subject, is Brigg's Arithmetica Logarithmica, 1624.

LOGISTICAL ARITHMETIC. See LOGISTICAL.

Numerous or Numeral ARITHMETIC, is that which teaches the calculus of numbers, or of abstract quantities; and is performed by the common numeral or Arabic characters.

POLITICAL ARITHMETIC, is the application of arithmetic to political subjects; such as, the strength and revenues of nations, the number of people, births, burials, &c. See POLITICAL ARITHMETIC. To this head may also be referred the doctrine of Chances, Gaming, &c.

ARITHMETIC OF RADICALS, RATIONALS, and IRRATIONALS. See RADICAL, &c.

ARITHMETIC OF SINES. See SINES.

SEXAGESIMAL or SEXAGENARY ARITHMETIC, is that which proceeds by sixties; or the doctrine of sexagesimal fractions: a method which, it is supposed, was invented by Ptolemy, in the 2d century; at least they were used by him. In this notation, the integral numbers from 1 to 59 were expressed in the common way, by the alphabetical letters: then sixty was called a Sexagesima Prima, and marked with a dash to the character 1, thus 1'; twice sixty, or 120, thus 11'; and so on to 59 times 60, or 3540, which is 11x'. Again, 60 times 60, or 3600, was called Sexageua

Secunda, and marked with two dashes, thus $\overline{1}$; twice 3600, thus $\overline{\overline{1}}$; and ten times 3600, thus $\overline{\overline{x}}$; &c. And in this way the notation was continued to any length. But when a number less than sixty was to be joined with any of the sexagesimal integers, their proper expression was annexed without the dash: thus 4 times 60 and 25, is $\overline{1}\overline{v}\overline{xxv}$; the sum of twice 60 and 10 times 3600 and 15, is $\overline{x}\overline{v}\overline{ii}\overline{xxv}$. So near did the inventor of this method approach to the Arabic notation: instead of the sexagesimal progression, he had only to substitute decimal; and to make the signs of numbers, from 1 to 9, simple characters, and to introduce another character, which should signify nothing by itself, but serving only to fill up places.—The Sexagenæ Integrorum were soon laid aside, in ordinary calculations, after the introduction of the Arabic notation; but the sexagesimal fractions continued till the invention of decimals, and indeed are still used in the subdivisions of the degrees of circular arcs and angles; except by the French, who now divide their circles into 400°; and were it not for the difficulty in overcoming the prejudices for old established customs, this method would doubtless be generally introduced, as it is much better in practice than that in common use.

Sam. Reyher has invented a kind of sexagenal rods, in imitation of Napier's bones, by means of which the sexagesimal arithmetic is easily performed.

A good treatise on the Greek or Sexagenary Arithmetic has lately (1808) been given by M. Delambre, in F. Peyrard's French translation of the works of Archimedes; and a very good account is given of the same in the Edinburgh Review, vol. 18, pa. 185.

Specious ARITHMETIC, is that which gives the calculus of quantities as designed by the letters of the alphabet: a method which was more generally introduced into algebra, by Vieta; being the same as literal arithmetic, or algebra.—Dr. Wallis has joined the numeral with the literal calculus; by which means he has demonstrated the rules for fractions, proportions, extraction of roots, &c; of which a compendium is given by himself, under the title of Elementa Arithmeticae, in the year 1698.

Tubular ARITHMETIC, is that in which the operations of multiplication, division, &c; are performed by means of tables calculated for that purpose: such as those of Herwart, in 1610; and my tables of powers and products, published by order of the Commissioners of Longitude, in 1781.

Tetractic ARITHMETIC, is that in which only the four characters 0, 1, 2, 3, are used. A treatise of this kind of arithmetic is extant, by Erhard or Echard Weigel. But both this and binary arithmetic are little better than curiosities, especially with regard to practice; as all numbers are much more compendiously and conveniently expressed by the common decuple scale.

Vulgar, or Common ARITHMETIC, is that which relates to integers and vulgar fractions.

Universal ARITHMETIC, is the name given by Newton to the science of algebra; of which he left at Cambridge an excellent treatise, being the text-book drawn up for the use of his lectures, while he was professor of mathematics in that university.

ARITHMETICAL, something relating to, or after the manner of arithmetic.

ARITHMETICAL Complement, of a logarithm, is what the logarithm wants of 10^6 &c; and the easiest way to find it is, beginning at the left hand, to subtract every figure from 9, and the last from 10. So, the arithmetical

complement of 8.2501396 is 1.7498604.—It is commonly used in trigonometrical calculations, when the first term of a proportion is not radius; in that case, adding all together, the logarithms of the 3d, 2d, and arithmetical complement of the 1st term.

ARITHMETICAL Instruments, or Machines, are instruments for performing arithmetical computations; such as Napier's bones, scales, sliding rules, Pascal's machine, &c.

ARITHMETICAL Mean, or Medium, is the middle term of three quantities in arithmetical progression; and is always equal to half the sum of the extremes. So, an arithmetical mean between 3 and 7, is 5; and between a and b , is $\frac{1}{2}a + \frac{1}{2}b$.

Also, an arithmetical mean among any number of quantities, is often found by adding the quantities all together, and then dividing the sum by the number of the terms. So, of the six numbers 1, 3, 4, 6, 7, 9, the sum is 30, which divided by 6, gives 5, for the mean or medium among them all.

ARITHMETICAL Progression, is a series of three or more quantities that have all the same common difference: as 3, 5, 7, &c, which have the common difference 2; and a , $a+d$, $a+2d$ &c, which have all the same difference d .

In an arithmetical progression, the chief properties are these: 1st, The sum of any two terms, is equal to the sum of every other two that are taken at equal distances from the two former, and equal to double the middle term when there is one equally distant between those two: so, in the series 0, 1, 2, 3, 4, 5, 6, &c, $0+6=1+5=2+4=$ twice 3 or 6.—2d, The sum of all the terms of any arithmetical progression, is equal to the sum of as many terms of which each is the arithmetical mean between the extremes; or equal to half the sum of the extremes multiplied by the number of terms: so, the sum of these ten terms 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, is $\frac{0+9}{2} \times 10$, or 9×5 , which is 45: and the reason of this will appear by inverting the terms, setting them under the former terms, and adding each two together, which will make double the same series;

$$\begin{array}{c} \text{thus } 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, \\ \text{inverted } 9, 8, 7, 6, 5, 4, 3, 2, 1, 0, \\ \text{sums } 9, 9, 9, 9, 9, 9, 9, 9, 9, 9; \end{array}$$

where the double series being the same number of 9's, or sum of the extremes, the single series must be the half of that sum.—3d, The last, or any term, of such a series, is equal to the first term, with the product added of the common difference multiplied by 1 less than the number of terms, when the series ascends or increases; or the same product subtracted when the series descends or decreases: so, of the series 1, 2, 3, 4, &c, whose common difference is 1, the 50th term is $1+1 \times 49$, or $1+49$, that is 50; and of the series 50, 49, 48, &c, the 50th term is $50-1 \times 49$, or $50-49$, which is 1. Also, if

- a denote the least term,
- z the greatest term,
- d the common difference,
- n the number of the terms,
- and s the sum of them all;

then the principal properties are expressed by these equations, viz.,

$$\begin{aligned} z &= a + d(n-1), \\ a &= z - d(n-1), \\ s &= (a+z)\frac{1}{2}n, \\ s &= [z - \frac{1}{2}d(n-1)] n, \\ s &= [a + \frac{1}{2}d(n-1)] n. \end{aligned}$$

Also, when the first term a , is 0 or nothing; the theorems become $z = d(n - 1)$, and $s = \frac{1}{2}zn$.

ARITHMETICAL Proportion, is when the difference between two terms, is equal to the difference between two other terms. So, the four terms, 2, 4, 10, 12, are in arithmetical proportion, because the difference between 2 and 4, which is 2, is equal to the difference between 10 and 12.—The principal property, besides the above, and which indeed depends upon it, is this, that the sum of the first and last, is equal to the sum of the two means: so 2 + 12, or the sum of 2 and 12, is equal to 4 + 10, or the sum of 4 and 10, which is 14.

ARITHMETICAL Ratio, is the same as the difference of any two terms: so, the arithmetical ratio of the series 2, 4, 6, 8, is 2; and the arithmetical ratio of a and b , is $a - b$.

ARITHMETICAL Scales, a name given by M. Buffon, in the Memoirs of the Acad, for 1741, to different progressions of numbers, according to which, arithmetical computations might be made. It has already been remarked above, that our common decuple scale of numbers was probably derived from the number of fingers on the two hands, by means of which the earliest and most natural mode of computation was performed; and that other scales of numbers, formed in a similar way, but of a different number of characters, have been devised; such as the binary and tetractic scales of arithmetic. In the memoir above cited, Buffon gives short and simple method to find, at once, the manner of writing down a number given in any scale of numbers whatever; with remarks on different scales. The general effect of any number of characters, different from ten, is, that by a smaller number of characters, any given number would require more places of figures to express or denote it by, than arithmetic calculations, by multiplication and division, would be easier, as the small numbers 2, 3, 4, &c, are easier to use than the larger 7, 8, 9; and by employing more than ten characters, though any given number would be expressed by fewer of them, yet the calculations in arithmetic would be more difficult, as by the larger numbers 11, 12, 13, &c. It is therefore concluded, on the whole, that the ordinary decuple scale is a good convenient medium among them all, the numbers expressed being tolerably short and compendious, and no single character representing too large a number. The same might also be said, and perhaps more, of a duodecimal scale, by twelve characters, which would express all numbers in a more compendious way than the decuple one, and yet no single character would represent a number too large to compute by; as is confirmed by the now common practice of extending the multiplication table, in school books, to 12 numbers or dimensions, each way, instead of 10; and every person is taught, with sufficient ease, to multiply and divide by 11 and 12, as easily as by 8 or 9 or 10. Another convenience might be added, namely, that the number 12 admitting of more submultiples than the number 10, there would be fewer expressions of interminate fractions in that way than in decimals. So that on all accounts, it is very probable that the duodecimal would be the best of any scale of numbers whatever.

ARITHMETICAL Triangle. See **TRIANGLE Arithmetical**.

ARMED. A magnet or loadstone is said to be armed, when it is capped, cased, or set in iron or steel; to make it take up a greater weight; and also readily to distinguish its poles.

It is surprising, that a little iron fastened to the poles of a magnet, shoud so greatly improve its power, as to make it even 150 times stronger, or more, than it is naturally, or when unarmed. The effect however, it seems, is not uniform; but that some magnets, by arming, gain much more, and others much less, than one would expect; and that some magnets even lose some of their efficacy by arming. In general however, the thickness of the iron armour ought to be nearly proportioned to the natural strength of the magnet; giving thick irons to a strong magnet, and to the weaker ones thinner: so that a magnet may easily be over-loaded.

The usual armour of a load-stone, in form of a right-angled parallelopipedon, consists of two thin pieces of iron or steel, of a square figure, and of a thickness proportioned to the goodness of the stone; the proper thickness being found by trials; always filing it thinner and thinner, till the effect be found to be the greatest possible.—The armour of a spherical load-stone, consists of two steel shells, fastened together by a joint, and covering a good part of the convexity of the stone. This also is to be filed away, till the effect is found to be the greatest.

Kircher, in his book *De Magnete*, says, that the best way to arm a load-stone, is to drill a hole through the stone, from pole to pole, in which is to be placed a steel rod of moderate length: this rod, he asserts, will take up more weight at the end, than the stone itself when armed in the common way. And Gassendus and Cabaeus prescribe the same method of arming. But Muschenbroek found, by repeated trials, that the usual armour, already mentioned, is preferable to Kircher's; and he gives the following directions for preparing it. When, by means of steel filings and a small needle, the poles of a magnet have been discovered, he directs that the adjacent parts should be rubbed or ground into parallel planes, without shortening the polar axis; and the magnet may be afterwards shaped into the figure of a cube or parallelopipedon, or any other figure that may be more convenient. Plates of the softest iron are then prepared, of the same length and breadth with the whole polar sides of the magnet: the thickness of which plates, so as that they may admit and convey the greatest quantity of the magnetic virtue, is to be previously determined by experiment, in a manner which he prescribes for the purpose. A thicker piece of iron is to be annexed at right angles to these plates, which is called *pes armaturæ*, the foot or base of the armour: then the plates, nicely smoothed and polished, are to be firmly attached to each of the polar sides, while the thicker part or base is brought into close contact with the lower part of the magnet. In this way, he says, almost all the magnetic virtue issuing from the poles, enters into the armour, is directed to the base, and condensed by means of its roundness, so as to sustain the greatest weight of iron. *Phys. Exper. and Geom. Dissert.* 1729, pa. 131.

ARMILLARY Sphere, a name given to the artificial sphere, composed of a number of circles of metal, wood, or paper, which represent the several circles of the system of the world, put together in their natural order. It serves to assist the imagination to conceive the disposition of the heavens, and the motion of the celestial bodies.

This sphere is represented at Plate 2, Fig. 6, where r and q represent the poles of the world, $\alpha\beta$ the equator, $\epsilon\lambda$ the ecliptic and zodiac, $\pi\alpha\gamma\delta$ the meridian, or the solstitial colure, τ the earth, fc the tropic of cancer, sr the tropic of capricorn, mn the arctic circle, ov the ant-

arctic, π and σ the poles of the ecliptic, and $\tau\sigma$ the horizon.

The Armillary sphere constructed by Dr. Long, in Pembroke-hall, Cambridge, was 18 feet in diameter; and will contain more than 30 persons sitting within it, to view, as from a centre, the representation of the celestial spheres. The lower part of the sphere, which is not visible to England, is cut off; and the whole apparatus is so contrived, that it may be turned round with as little labour as is employed to wind up a common jack. See also Mr. Ferguson's sphere, in his Lectures, p. 194.

ARMILLARY Trigonometer, an instrument first contrived by Mr. Mungo Murray, and improved by Mr. Ferguson, consisting of five semicircles; viz, meridian, vertical circle, horizon, hour circle, and equator; so adapted to each other by joints and hinges, and so divided and graduated, as to serve for expeditiously resolving many problems in astronomy, dialling, and spherical trigonometry. The drawing, description, and method of using it, may be seen in Ferguson's Tracts, pa. 80, &c.

ARTILLERY, the heavy equipage of war; comprehending all sorts of large fire-arms, with their appurtenances; as cannon, mortars, howitzers, caronnades, balls, shells, petards, musquets, carbines, &c; being what is otherwise called Ordnance. The term is also applied to the larger instruments of war used by the ancients, as the catapult, balista, battering-ram, &c.

The term Artillery, or Royal Artillery, is also applied to the persons employed in that service; as also to the art or science itself; and formerly it was used for what is otherwise called Pyrotechnia, or the art of fire-works, with the apparatus and instruments belonging to the same.

There have been many authors on the subject of artillery; the principal of which are, Bucherius, Braunius, Tartalea, Collado, Sardi, Uiano, Hanzelet, Digges, Moretti, Simienowitz, Miech, d'Avelour, Manesson, Mallet, St. Julien; and the later authors, of still more consequence, are Belidor, St. Remy, le Blond, Valiere, Morogue, Puget, Coudray, Robins, Muller, Euler, Antoni, Tignola, Scheele; to which may be added the extensive and accurate experiments published in the 2d and 3d volumes of my Tracts, and in the Philos. Trans. for 1778.

Park of ARTILLERY, is that place in a camp which is set apart for the artillery, or large fire-arms.

Train or **Train of ARTILLERY**, a number of pieces of ordnance, mounted on carriages, with all their furniture fit for marching. To this commonly belong mortars, canon, balls, shells, &c.—There are trains of artillery in most of the royal magazines; as in the Tower, at Portsmouth, Plymouth, &c, but, above all, at Woolwich, from whence the ships commonly receive their ordnance, and where they are all completely proved before they are received into the public service.

The officers and men of the artillery were formerly called also the Train of Artillery, but are now called the Royal Regiment of Artillery; consisting at present of ten battalions, and several troops of Horse or Cavalry Artillery.

ASCENDING, in Astronomy, a term used to denote any star, or degree, or other point of the heavens, rising above the horizon.

ASCENDING Latitude, is the latitude of a planet when going towards the north.

ASCENDING Node, is that point of a planet's orbit where it crosses the ecliptic, in proceeding northward. It is otherwise called the Northern Node, and is denoted by

this character \otimes , representing a node, or knot, with the larger part upwards; and the same character reversed is used to denote the opposite, or Descending Node \otimes .

ASCENDING Signs, are such as are upon their ascent, or rise, from the nadir or lowest point of the heavens, towards the zenith, or highest point.

ASCENSION-DAY, otherwise called *Holy Thursday*, is festival of the church, held 10 days before Whit-sunday, in memory of our Saviour's Ascension.

ASCENSION, in Astronomy, is either Right or Oblique.

Right ASCENSION of the sun, or of a star, is that degree of the equinoctial, accounted from the beginning of Aries, which rises with them, in a right sphere.—Or, Right Ascension, is that point of the equinoctial, counted before, which comes to the meridian with the sun or star, or other point of the heavens. And the reason of thus referring it to the meridian, is, because this is always at right angles to the equinoctial; whereas the horizon is so only in a right or direct sphere.—The right ascension stands opposed to the right descension; and is similar to the longitude of places on the earth. All the fixed stars, &c, which have the same right ascension, that is, which are at the same distance from the first point of Aries, or, which comes to the same thing, which are in the same meridian, rise at the same time in a right sphere, that is, to the people who live at the equator. And if they be not in the same meridian, the difference between their times of rising, or of coming to the meridian of any place, is the precise difference of their right ascension.—But, in an oblique sphere, where the horizon cuts all the meridians obliquely, different points of the same meridian never rise or set together: so that two or more stars on the same meridian, or having the same right ascension, never rise or set at the same time in an oblique sphere; and the more oblique the sphere is, the greater is the interval of time between them.

To find the right ascension of the sun, stars, &c, by trigonometry, say, As radius is to the cosine of the sun's greatest declination, or obliquity of the ecliptic, so is the tangent of the sun's or star's longitude, to the tangent of the right ascension.

RIGHT ASCENSION of the *Mid-heaven*, often used by astronomers, especially in calculating eclipses by means of the nonagesimal degree, is the right ascension of that point of the equator which is in the meridian; and it is equal to the sum of the sun's right ascension and the horary angle or true time reduced to degrees, or to the sum of the mean longitude and mean time.

Oblique ASCENSION, is an arch of the equator intercepted between the first point of Aries, and that point of the equator which rises together with the star, &c, in an oblique sphere.—The oblique ascension is counted from west to east; and is greater or less, according to the various obliquity of the sphere.—To find the oblique ascension of the sun, see **ASCENSIONAL** and **GLOBE**.

The *Arch of Oblique Ascension*, is an arch of the horizon intercepted between the beginning of Aries, and the point of the equator which rises with a star or planet, in an oblique sphere; and it varies with the latitude of the place.

Refraction of ASCENSION and DESCENSION. See **REFRACTION**.

ASCENSIONAL DIFFERENCE, is the difference between the right and oblique ascension of the same point on the surface of the sphere. Or it is the time the sun rises or sets before or after 6 o'clock.

To find the ascensional difference, having given the sun's declination and the latitude of the place, say, As radii is to the tangent of the latitude, so is the tangent of the sun's declination, to the sine of the ascensional difference sought. The sun's ascensional difference converted into time, shows how much he rises before, or sets after, 6 o'clock. When the sun has north declination, the right ascension is greater than the oblique; but the contrary, when the sun has south declination; and the difference, in either case, is the ascensional difference.

ASCENT, the motion of a body from below tending upwards; or the continual recess of a body from the earth, or from some other centre of force. And it is opposed to descent, or motion downwards.

An acclivity is also sometimes called an ascent, as a declivity is called a descent.

The Peripatetics attributed the spontaneous ascent of bodies to a principle of levity, inherent in them. But the moderns have demonstrated that there is no such thing as spontaneous levity; and they show, that whatever ascends, does so by virtue of some external impulse or extrusion. Thus it is that smoke, and other rare bodies, ascend in the atmosphere; and oil, light woods, &c, in water; not by any inherent principle of levity, but superior gravity, or pressure of the medium in which they ascend and float.

The ascent of light bodies in heavy mediums, is produced after the same manner as the ascent of the lighter scale of a balance. It is not that such scale has an internal principle, by which it immediately tends upwards; but it is impelled upwards by the preponderancy of the other scale; the excess of the weight in the one having the same effect, by augmenting its impetus downwards, as so much real levity in the other; because the tendencies mutually oppose each other, and action and reaction are always equal.—See this farther illustrated under the articles **FLUID**, and **SPECIFIC GRAVITY**.

ASCENT of Bodies on Inclined Planes. See the doctrine and laws of them under **INCLINED PLANE**.

ASCENT of Fluids, is particularly understood of their rising above their own level, between the surfaces of nearly contiguous bodies, or in slender capillary glass tubes, or in vessels filled with sand, ashes, or the like porous substances. Which is an effect that takes place as well in vacuo, as in the open air, and in bent, as well as straight tubes. Indeed some fluids ascend swifter than others, as spirit of wine, and oil of turpentine; and some rise after a different manner from others. The phenomenon, with its causes, &c, in the instance of capillary tubes, will be treated more at large under **CAPILLARY TUBE**.

As to planes: Two smooth polished plates of glass, metal, stone, or other matter, being placed almost contiguous, have the effect of several capillary tubes, and the fluid rises in them accordingly: the same may be said of a vessel filled with sand, &c; the various small interstices of which form, as it were, a kind of capillary tubes. So that the same principle accounts for the appearance in them all. And to the same cause may be ascribed the ascent of the sap in vegetables. And on this subject Sir Isaac Newton says, “If a large pipe of glass be filled with sifted ashes, well pressed together, and one end dipped into stagnant water, the fluid will ascend slowly in the ashes, so as in the space of a week or fortnight, to reach the height of 30 or 40 inches above the stagnant water. This ascent is wholly owing to the action of those particles of the ashes which are on the surface of the elevated water; those

within the water attracting as much downwards as upwards: it follows, that the action of such particles is very strong; though being less dense and close than those of glass, their action is not equal to that of glass, which keeps quicksilver suspended to the height of 60 or 70 inches, and therefore acts with a force which would keep water suspended to the height of above 60 feet. By the same principle, a sponge sucks in water, and the glands in the bodies of animals, according to their several natures and dispositions, imbibe various juices from the blood.” Optics, p. 367.

Again, if a drop of water, oil, or other fluid, be dropped upon a glass plane, perpendicular to the horizon, so as to stand without breaking, or running off; and another plane touching it at one end, be gradually inclined towards the former, till it touch the drop; then will the drop break and move along towards the touching end of the planes; and it will move the faster in proportion as it proceeds farther, because the distance between the planes is constantly diminishing. And after the same manner, the drop may be brought to any part of the planes, either upward or downward, or sideways, by altering the angle of inclination.

Lastly, if the same planes be so placed, as that two of their sides meet, and form a small angle, the other two being only kept apart by the interposition of some thin body; and thus immersed in a fluid, tinged with some colour to render it visible; the fluid will ascend between the planes, and that the highest where the planes are nearest; so as to form a curve line which is found to be a true hyperbola, of which one of the asymptotes is the line of the fluid, the other being a line drawn along the touching sides.

And the physical cause of all these phenomena, is the same power of attraction.

ASCENT of Vapour. See **CLOUD** and **VAPOUR**.

ASCENT, in Astronomy, &c. See **ASCENSION**.

ASCI, are those inhabitants of the globe, who, at certain times of the year, have no shadow. Such are the inhabitants of the torrid zone, who twice a year having the sun at noon in their zenith, have then no shadow.

ASELLI, two fixed stars of the fourth magnitude, in the constellation **Cancer**.

ASH-WEDNESDAY, the first day of Lent, supposed to have been so called from a custom in the church, of sprinkling ashes that day on the heads of penitents then admitted to penance.

APECT, is the situation of the stars and planets in respect of each other. Or, in Astrology, it denotes a certain configuration and mutual relation between the planets, arising from their situations in the zodiac, by which it is supposed that their powers are mutually either increased or diminished, as they happen to agree or disagree in their active or passive qualities. Though such configurations may be varied and combined a thousand ways, yet only a few of them are considered. Hence, Wollius more accurately defines aspect to be, the meeting of luminous rays emitted from two planets to the earth, either posited in the same right line, or including an angle which is an aliquot part, or some number of aliquot parts, of four right angles, or of 360 degrees.

The doctrine of aspects was introduced by the astrologers, as the foundation of their predictions. And hence Kepler defines aspect to be, an angle formed by the rays of two planets meeting on the earth, capable of exciting some natural power or influence.

The ancients reckoned five aspects, viz. *conjunction*, *sextile*, *quartile*, *trine*, and *opposition*.

Conjunction is denoted by this character δ , and is when the planets are in the same sign and degree, or have the same longitude.

Sextile is denoted by $*$, and is when the planets are distant by the 6th part of a circle, or 2 signs, or 60 degrees.

Quartile is denoted by \square , and is when the planets are distant $\frac{1}{4}$ of the circle, or 90 degrees, or 3 signs.

Trine is denoted by Δ , and is when the planets are distant by $\frac{1}{3}$ of the circle, or 4 signs, or 120 degrees.

Opposition is denoted by \circ , and is when the planets are in opposite points of the circle, or differ by $\frac{1}{2}$ the circle, or 6 signs, or 180 degrees of longitude.

Or their characters and distances are as in this following tablet.

NAME.	CHARACTER.	DISTANCE.
Conjunction	δ	$0^{\circ} = 0^{\circ}$
Sextile	$*$	$60 = 2$
Quartile	\square	$90 = 3$
Trine	Δ	$120 = 4$
Opposition	\circ	$180 = 6$

These intervals are reckoned according to the longitudes of the planets; so that the aspects are the same, whether the planet be in the ecliptic or out of it.

ASPERITY, signifies the inequality or roughness of the surface of any body; by which some parts of it are more prominent than the rest, so as to hinder the hand, &c, from passing over it with ease and freedom; and thus producing what is called friction.—*Asperity*, or roughness, stands opposed to smoothness, evenness, &c.

According to the relations of Vermausen, the blind man so celebrated for distinguishing colours by the touch, it seems that every colour has its peculiar degree and kind of asperity. He makes black the roughest, as it is the darkest of colours; but the others are not smoother in proportion as they are lighter; that is, the roughest do not always reflect the least light: for, according to him, yellow is two degrees rougher than blue, and as much smoother than green. See COLOURS.

ASSIGNABLE Magnitude, is used for any finite magnitude that can be expressed or denoted. And,

Assignable Ratio, for any expressible ratio.

ASSUMPTION, a feast celebrated in the Romish church, in honour of the miraculous ascent of the Holy Virgin, as they describe it, body and soul, into heaven. It is kept on the 15th of August.

ASSURANCE on Lives, a compact by which security is granted for the payment of a certain sum of money on the expiration of the life on which the policy is given, in consideration of such a previous payment made to the assurer as is accounted a sufficient compensation for the loss and hazard to which he exposes himself.

The sum at which this compensation should be valued, depends principally on these two circumstances, viz. 1st, On the rate of interest given for the use of money; and 2d, On the probability of the duration of the life assured, and the values of annuities. For, 1st, If the interest of money be high, the value of the insurance will be proportionally low, and the contrary; because the higher the rate of interest, the less will be the present value which amounts to a certain proposed sum in any given time. Also, if the probability of the duration of life be high, the value of the assurance will again be proportionably low,

Vol. I.

and the contrary; because the longer the time is, the less will be the principal which will amount to any assigned sum. Thus, if it be required to know the premium or present value, to be given for 100 pounds to be received at the end of any time, as suppose 10 years; then, if the interest of money be at the rate of 5 per cent, the answer, or present premium, would be $61l\ 7s\ 10d$; but at 4 per cent, it would be $67l\ 11s\ 1d$; and at 3 per cent, it would amount to $74l\ 8s\ 2d$. Again, suppose it were required to assure 100*l* on a life, for any time, for instance 1 year; that is, let 100*l* be supposed to be payable a year hence, provided a life of a given age fails in that time: here it is evident that, whatever be the rate of interest, the less the probability of the life failing within the year, the less the risk is, and the less the premium ought to be. In effect, the rate of interest being 5 per cent, if it were sure that the life would fail in that year, the value of the assurance would be the same as the present value of 100*l*, payable at the end of the year, which is $95l\ 4s\ 9d$.

But, if it be an equal chance whether the life does or does not fail in the year, in which case the probability of failing is $\frac{1}{2}$; then the value of the assurance will be but half the former value, or $47l\ 12s\ 4\frac{1}{2}d$. Or if the odds against its failing be as 2 to 1, that is, if one person out of every 3 die at the age of the proposed life, the probability of dying being only $\frac{1}{3}$, the value of the assurance will be $\frac{1}{3}$ of the first value, or $31l\ 14s\ 11d$. And if the odds be 19 to 1, or one person die out of 20, of that age, the probability of dying will be $\frac{1}{20}$, and the value of the assurance will also be $\frac{1}{20}$ of the first value, or $4l\ 15s\ 3d$ nearly. Lastly, if only one person die out of 50 at the given age, the probability of dying will be $\frac{1}{50}$, and the value of the assurance will be accordingly only $\frac{1}{50}$ of the first sum, or $1l\ 18s\ 1d$: the interest of money being all along considered as after the rate of 5 per cent.—Now, according to Dr. Halley's table of observations, one person dies out of 3, at the age of 87; one in 20 at the age of 64; and one in 50 at the age of 39: It follows, therefore, that the value of the assurance of 100*l*, for one year, on a life aged 87, is $31l\ 14s\ 11d$; on a life aged 64, it is $4l\ 15s\ 3d$; and on a life aged 39, it is $1l\ 18s\ 1d$, reckoning interest at 5 per cent. But if interest were rated at 3 per cent, these values would be $32l\ 7s\ 3d$, and $4l\ 17s\ 1d$, and $1l\ 18s\ 10d$.

When a life is assured for any number of years; the premium or value may be paid, either in one single present payment; in consequence of which the sum assured will become payable without any farther compensation, whenever, within the given term, the life shall happen to drop: or the value may be paid in annual payments, to be continued till the failure of the life, should that happen within the term; or, if not, till the determination of the term. And the determination of the value of assurance, in all cases, is to be made out from the rules for computing annuities on lives; the principal writers on which are Halley, De Moivre, Simpson, Simart, Kerschoom, De Parcieux, Price, Morgan, Maseres, and Baily. See also LIFE ANNUITIES, REVERSIONS, &c.

Assurances may be made either on single lives; as above explained; or they may be made on any number of joint lives, or on the longest of any lives; that is, an assurer may bind himself to pay any sums at the extinction of any joint lives, or the longest of any lives, or at the extinction of any one or two of any number of lives. There are further assurances on survivorships; by which is meant an obligation, for the value received, to pay a given sum

or annuity, provided a given life shall survive any other given life or lives. For which see SURVIVORSHIP.

The principal offices for making these insurances, in England, are the London and the Royal Exchange Assurance Offices; the Amicable Society, incorporated for a perpetual Assurance Office; the Society for equitable Assurances on Lives and Survivorships; the Westminster Society for granting Annuities and insuring Money on Lives; the Phoenix fire-office; the Westminster fire-office; the Life-assurance Society, for widows and female relations; the British fire-office; the Pelican life-insurance; the Landable Society, for widows; the Imperial Insurance Company; the Globe; the Albion; the Rock; the Provident Institution; the Philanthropic; the Hope; the County fire-office; the Eagle; the London Life Association; and the Atlas.

Most of these offices, besides various extensive companies in the country, make also insurances on houses, goods, ships, &c, from fire and damages, &c. These articles of assurances are commonly divided into 3 classes: first, common assurances, which are made at 2s per cent. per annum; 2d, hazardous assurances, at 3s; and 3dly, doubly hazardous, at 5s per cent. per annum: and the mode of classification may be learned from the proposals of any of the companies. Besides these rates, a duty of 1s 6d on every 100*l* was imposed in 1782, which was increased in 1797 to 2s per cent., and in 1804 to 2s 6d per cent. From the produce of this duty, an estimate has been formed of the total amount of property assured from fire in Great Britain, which appears to have been at several periods nearly as follows:

In 1785 - - - - -	£ 125 millions.
1789 - - - - -	142
1793 - - - - -	167
1797 - - - - -	184
1801 - - - - -	223
1806 - - - - -	260

As to the assurances on lives, the premium or rates of the different companies are nearly alike; as indeed they must be if founded on correct principles, and equally advantageous to the public; and the following tables of the rates are nearly the same in all.

A Table of Premiums for assuring the Sum of one hundred Pounds upon the Life of any healthy Person, from the Age of Eight to Sixty-seven.

From the above specimen of premiums, the reader will easily judge of the proportional premium for any intermediate age.

ASTERISM, the same with constellation, or a collection of many stars, which are usually represented on globes by some particular image or figure, to distinguish the stars which compose this constellation from those of others.

ASTRÆA, a name given by some to the sign Virgo, by others called Erigone, and sometimes Isis. The poets feign that Justice quitted heaven to reside on earth, in the golden age; but, growing weary of the iniquities of mankind, she left the earth, and returned to heaven, placing herself in that part of the zodiac called Virgo, where she became a constellation of stars, and from her orb still looks down on the ways of men. Ovid. Metam. lib. i. ver. 149.

ASTRAGAL, in Architecture, a small round moulding, which encompasses the top of the fust or shaft of a column, like a ring or bracelet. The shaft always terminates at top with an astragal, and at bottom with a fillet, which in this place is called *ozia*.

ASTRALGAL, in Gunnery, is a kind of ring or moulding on a piece of ordnance, at about half a foot distance from the muzzle or mouth; serving as an ornament to the gun, as the former does to a column.

ASTRAL, something belonging to or depending on the stars.

ASTRAL Year, or Sidereal Year. See YEAR.

ASTRODICTICUM, an astronomical instrument invented by M. Weigel, by means of which many persons shall be able to view the same star at the same time.

ASTROLABE, from ἀστρος, star, and λαβειν, I take; alluding to its use in taking, or observing, the stars. The Arabians call it in their tongue *astharlab*; a word formed by corruption from the common Greek name.

This name was originally used for a system or assemblage of the several circles of the sphere, in their proper order and situation with respect to each other. And the ancient instruments were much the same as our armillary spheres.

The first and most celebrated of this kind, was that of Hipparchus, which he made at Alexandria, the capital of Egypt, and lodged in a secure place, where it served for divers astronomical operations. Ptolemy made the same use of it: but as the instrument had several inconveniences, he contrived to change its figure, though perfectly natural, and agreeable to the doctrine of the sphere; and to reduce the whole astrolabe to a plain surface, to which he gave the name of the Planisphere. Hence,

ASTROLABE is used among the moderns for a Planisphere, or a stereographic projection of the circles of the sphere on the plane of one of the great circles; which is usually either the plane of the equinoctial, the eye being then placed in the pole of the world; or that of the merid-

dian, the eye being supposed in the point of intersection of the equinoctial and horizon; or on that of the horizon.

The Astrolabe has been treated at large by Stöffler, Gemma Frisius; Clavius, and our poet Chaucer, who wrote a long and learned tract upon it, and indeed on the whole practice of astronomy, as the art stood in his day. For a farther account of the nature and kinds of it, see the article PLANISPHERE.

ASTROLABE, OR SEA ASTROLABE, more particularly denotes an instrument chiefly used for taking altitudes at sea; as the altitude of the pole, the sun, or the stars.

The common Astrolabe, represented Plate 2, fig. 7, consists of a large brass ring, about 15 inches in diameter, whose limb, or a convenient part of it, is divided into degrees and minutes. It is fitted with a moveable label or index, which turns upon the centre, and carries two sights; and having a small ring, at A, to hang it by in time of observation.

To make use of the Astrolabe in taking altitudes; suspend it by the ring A, and turn it to the sun, &c, so as that the rays may pass freely through both the sights r and s; then will the label cut or point out the altitude on the divided limb. There are many other uses of the Astrolabe; of which Clavius, Henrion, and others have written very largely.

The Astrolabe, though now come into disuse, is by many esteemed equal to any other instrument for taking the altitude at sea; especially between the tropics, where the sun comes near the zenith.

ASTROLOGICAL, something relating to Astrology.

ASTROLOGY, the pretended art of foretelling future events, from the positions, aspects, and influences of the heavenly bodies. The word is compounded of *ἀστρος*, star, and *λογία*, discourse; whence, in the literal sense of the term, astrology should signify no more than the doctrine or science of the stars: this indeed was its original acceptation, and constituted the ancient astrology; which consisted formerly of both the branches now called astronomy and astrology, under the name of the latter only; and for the sake of making judiciary predictions it was, that astronomical observations, properly so called, were chiefly made by the ancients. And though the two branches be now perfectly separated, and that of astrology almost universally rejected by men of real learning, this has but lately been the case, as their union subsisted, in some degree, from Ptolemy till Kepler, who had a strong bias towards the ancient astrology.

Astrology may be divided into two branches, natural and judiciary.

To **NATURAL ASTROLOGY** belongs the predicting of natural effects; such as the changes of weather, winds, storms, hurricanes, thunder, floods, earthquakes, &c. But this art properly belongs to Physiology, or Natural Philosophy; and is only to be deduced, a posteriori, from phenomena and observations. And for this kind of astrology it is that Mr. Boyle makes an apology in his History of the Air. Its foundation and merits may be gathered from what is said under the articles AIR, ATMOSPHERE, and WEATHER.

Judicial, or Judiciary ASTROLOGY, which is what is commonly and properly called astrology, is that which professes to foretel moral events, or such as have a dependence on the free will and agency of man; as if they were produced or directed by the stars.

The professors of this kind of astrology maintain,

"That the heavens are one great volume or book, wherein God has written the history of the world; and in which every man may read his own fortune, and the transactions of his time. The art," say they, "had its rise from the same people as astronomy itself: while the ancient Assyrians, whose serene unclouded sky favoured their celestial observations, were intent on tracing the paths and periods of the heavenly bodies, they discovered a constant, settled relation of analogy, between them and things below; and hence were led to conclude these to be the Parcae, the Destinies so much talked of, which preside at our births, and dispose of our future fate."

"The laws therefore of this relation being ascertained by a series of observations, and the share each planet has therein; by knowing the precise time of any person's nativity, they were enabled, from their knowledge in astronomy, to erect a scheme or horoscope of the situation of the planets, at that point of time; and hence, by considering their degrees of power and influence, and how each was either strengthened or tempered by some other, to compute what must be the result thereof."

Judicial Astrology, it is commonly said, was invented in Chaldea, and from thence transmitted to the Egyptians, Greeks, and Romans; though some insist that it was of Egyptian origin, and ascribe the invention to Cham. But it is to the Arabs that we owe it. At Rome the people were so infatuated with it, that the astrologers, or, as they were then called, the mathematicians, maintained their ground in spite of all the edicts of the emperors to expel them out of the city. See GENETHLIACI.

Among the Indians, the bramins, who introduced and practised this art in the East, have hereby made themselves the arbiters of good and evil hours, which gives them great authority: they are consulted as oracles; and they have taken care always to sell their answers at good rates.

The same superstition has prevailed in more modern ages and nations. The French historians remark, that in the time of queen Catharine de Medicis astrology was so much in vogue, that the most inconsiderable thing was not to be done without consulting the stars. And in the reigns of king Henry III and IV of France, the predictions of astrologers were the common theme of the court conversation. And this predominant humour in that court was well rallied by Barclay, in his Argenis, lib. 2, on occasion of an astrologer, who had undertaken to instruct king Henry in the event of a war which was then threatened by the faction of the Guises.

History of Astrology.—Nothing could be more vain, ridiculous, and absurd, than the pretended science of astrology; yet nothing, perhaps, could possibly have led men to a more diligent inquiry into, and finally to a knowledge of, the laws that regulate the motions of the heavenly bodies. Thus it has been said, that astrology was the daughter of ignorance, and the mother of astronomy; and certainly, if it was not the offspring of passive ignorance, it must be acknowledged to have derived its origin from the natural vanity and credulity of the human mind, aided perhaps by the coincidence of some accidental circumstances, such as an eclipse, the appearance of a comet, or other celestial phenomenon, at the time of any remarkable calamity, the death of a prince, or the defeat of an army; which being once observed, nothing more was necessary, in this infant state of the reasoning faculty of man, to lead him to a belief that all great events were connected with the motion of the heavenly bodies, that the death of princes

was always announced by some celestial phenomenon; and finally, that every man had his destiny written in the heavens, in which might be read all the physical and political events of his life.

Whether or not, astronomical observations were made, before they were thought necessary to astrological predictions, we have now no means of determining; but at all events, we know that many were made with no other view, and in consequence of which the knowledge of astronomy was advanced, if it did not derive its immediate origin from astrology. It is also probable, that to the same frivolous motive, we are indebted for the preservation of so many of the learned works of Greece, which have been handed down to us. For, as a celebrated author justly observes, "What could be the charms of truth, purely geometrical, to a people sunk for so many ages in the deepest abyss of ignorance and superstition;" but that arithmetic, geometry and even optics, such as it was, were the necessary steps to astronomy, and this again was the preliminary to every astrological prediction? In this respect astrology, if not the mother of astronomy, was at least its nurse, and the preserver of many of the other sciences: for which reason its name may still be preserved from that oblivion which, considered as a science, it so justly merits. At what time, or in what country this pretended science first originated, are alike unknown; or whether it may not have been invented, neglected, and revived, in different countries, at different periods, according as the sciences were in their infancy, plenitude, or decline. Indeed the latter seems the most probable, as there were different modes of drawing horoscopes in different nations; which seems to indicate that they had not all obtained it from one and the same original. However this may be, we find its traces in the ancient records and manuscripts of every nation, where those records are to be found; in India, China, Chaldea, Greece, Egypt, Arabia, and Europe. In short, in every country where the sciences have been introduced, the footsteps of astrology are likewise to be discovered.

In India the pretended knowledge of astrology, or the art of divination, remained entirely with the bramins, who were too cunning to promulgate its mysteries, being aware that it would be the most probable means of detecting the imposition, and their interest was too much involved in the deception, for them not to be anxious to keep the secret to themselves: it was not only in their hands a source of emolument and riches, but likewise a convenient instrument for securing the reverence of the people. They not only professed a knowledge of judicial astrology, but also as it regarded meteorology; publishing yearly an almanac or panjamgam, in which every week, and hour, both of day and night, were set aside for performing certain avocations in agriculture and other concerns of life: they annually presented to the prince a prediction of events for the following year; and such as were found to deceive three times were condemned to silence, but the others who were fortunate in their predictions, enjoyed every distinction that was due to such profound knowledge. The Chinese had, and still continue to have, their astrologers; and many records, both of judicial, and natural or meteorological astrology of very great antiquity, still remain. The following is a remarkable instance of the estimation in which astrology was held in China, and of the brutal barbarity and ignorance of their emperor Tsin-chi-hoang, who in the year 246, after having re-united under one head all the little states, into which the empire had been divided

by intestine broils, and presuming that the sword was sufficient to secure what it had already acquired, he ordered every book to be burnt, except those relating to agriculture, medicine, and astrology; three sciences which, it thus appears, he thought equally serviceable to the nation; while all those relating to history and pure astronomy were destroyed in the barbarous conflagration. But of all the professors of this doctrine, none appear to have been so celebrated as the Chaldeans, even the name of Chaldean and Astrologer became as it were synonymous; and according to their records it has been practised among them for thousands of ages: even taking their years for days, which, according to some modern authors, is what they are supposed to represent, they amount to more than 2000 years before the birth of Christ. Zoroaster is said to have been the founder of astrology among the Chaldeans; he was followed by Hostanes, from whom the Greeks and Egyptians are supposed to have received this doctrine. Belezes, another noted Chaldean astrologer, became famous for having predicted to Arbasces the victory that he afterwards gained over Sardanapalus, a prediction by no means difficult, when we consider the tyranny and debauchery of the latter, which caused him to be abhorred and despised, both by his troops and his nation. But thus it frequently happened, that the prediction of an event, which required only a little foresight and knowledge of mankind to know nearly to a certainty the result, was the means of raising men to celebrity, and they were generally too cunning to undeceive the wondering multitude. As to the Greeks, it does not appear that they were so much infatuated with the belief of judicial astrology, as the nations we have already mentioned; but to what is called meteorological astrology, they paid particular attention; various predictions of this kind having been given in the Greek calendars by Eudoxus, Callippus, Aratus, Hipparchus, and other authors of eminence. It is a long time after this, that we find some account of the destiny of particular men pretended to be predicted from an inspection of the stars. We must not however omit to mention, that there are two works on the subject of judicial astrology under the name of Ptolemy; but it appears there is some reason to suspect that they are not his works, and for the honour of the author of the Almagest, it is to be hoped they are not.

Next to the Chaldeans, the Egyptians were certainly the most celebrated astrologers; their belief in this doctrine being carried to the highest degree of enthusiasm: all that we suppose to depend upon our will, or on our determination, they believed to be connected with the motion of the stars, and that our destinies are written in the heavens, wherein may be read our thoughts, inclinations, constitutions, and every event of our lives.

Till about the commencement of the Christian era, or a little before, astrology was circumscribed to the East, and to Egypt; but about this time it invaded the Roman empire, and Rome itself was inundated with the professors of this imaginary science. It was in vain that the senate issued decrees against them, under the name of Chaldeans, astrologers, or mathematicians, they having arrogated to themselves the latter appellation; thus degrading one of the noblest sciences, by associating it with their ridiculous doctrine: but notwithstanding these decrees, they still maintained themselves, through the support which they experienced from individuals, and some even gained great celebrity for their pretended knowledge and ability, as Nigidius Figilus Trassylus, the astrologer to Tiberius; Ta-

runtius Firmanus, the friend both of Cicero and Varro; and particularly the poet Manilius, whose poem entitled *Astronomicum sive Matheoseos*, lib. viii., published in 1551, with some Greek and Arabian works of the same kind, is a sort of course of judicial astrology, having scarcely any thing in it relating to pure astronomy. Nigidius became celebrated for predicting to Octavius, father of Augustus, that the infant would be one day master of Rome. Trasylus was the constant attendant of Tiberius; and all those persons whom the latter had reason, or thought that he had reason to fear, he caused their horoscope to be drawn, and if, as it frequently happened, their stars announced them to be ambitious, or that they had any pretensions to the empire, they were put to death: such was the effect of this most abominable, and disgusting doctrine; and who knows how many may thus have innocently suffered death, from such predictions, through the tyranny, ignorance, and superstition of princes and the rulers of nations? Under these circumstances, astrologers could not fail of having a complete ascendancy over the people; as it must have been very dangerous to offend those, who could make the stars say what they pleased, to gain the favour of their prince, or to gratify their own private revenge. It should be observed that this art was not always limited to predicting events from certain periods of time being given, but they performed also the converse of the proposition; that is, by knowing the events, they pretended to discover the time; this indeed was an easier problem, at least they were not so likely to be belied by the event, as frequently happened in other cases. Thus Varro having demanded of Firmanus the time of the birth of Romulus, from the events recorded of his life, the astrologer discovered that he was conceived the first year of the second Olympiad, about 3 o'clock of the 23d day of the Egyptian month Chæac, that is, the 23d of December, and that he was born under the influence of the sun, the 21st of September following; and moreover, that Rome was founded by him on the 9th of April, when the moon was in the sign libra: hence also he determined the fate of the city; for cities and towns had their horoscopes as well as men; such was the pitch to which this most ridiculous science was carried.

The Arabs are another people who made a considerable figure in the history of judicial astrology. All the knowledge they had of astronomy was made entirely subservient to that doctrine, and their history is filled with traits on this subject; a circumstance which proves their great predilection for this pretended science.

The number of Arabian authors, who have written on astrology, would form a long catalogue; but we shall only mention some of the most celebrated. Such were Mesalah and Alchindi, both Jews; and Ali-ben-redoan, who was so much admired by Cardan; Alcabitius, whose work was published in 1502 in quarto, and afterwards in folio in 1503 and 1512; Alfarabius; Alboreen; Aliaben Ragel; Albubator; Almansor; and a great number of others, worthy of the obscurity in which they are placed at this day. Jacob Alchindi the Jew enjoyed great celebrity under the reign of Almansor; but the Arabs, jealous of the favour which he experienced, accused him of magic, which led to a violent dispute between him and a mosulian doctor, till at last they defied each other's art. This being put to the test, these two learned professors each drew a circle about himself, to which they attributed a magical power; and thus posited, the doctor, by way of challenge, wrote

two words on a piece of paper which he sealed up and delivered to the calif, and defied Alchindi to divine what they were: this was no easy task for Jacob; but still he cunningly applied himself to his books and instruments; and then, with all the importance of self-consequence, answered, that the first of these words was a plant, and the other an animal; the calif having opened the paper, he, and all present, were struck with astonishment to find the words *assa, mousa*. This lucky guess gave Jacob such a decided advantage over his confounded adversary, that Albumazar, one of the doctor's pupils, was so much hurt at the disgrace of his master, that hiding a dagger under his cloak, he was going to kill Alchindi; when the latter, not duly apprised of his design, called out with a stern voice, " You come to slay me; quit this design and the poniard that you carry, and I will teach you astronomy." Astonished at these words he let fall the dagger, and became one of Alchindi's most zealous disciples, and afterwards one of the most celebrated astrologers. He wrote a treatise on the conjunction of the planets, in order to read, as it were, the destiny of the earth; to find the time of its origin, and the end of the world. He predicted the fates of the different religions; the Christian religion was to subsist for 1460 years, that of Mahomet 544 years; but all these predictions, like most others of a similar nature, have been contradicted by facts.

In 1179, the Arabian astrologers predicted for the year 1186, a dreadful inundation, and such terrible tempests, that would overthrow every thing in their course, in consequence of a conjunction of five planets, and a great eclipse of the sun. During seven years alarm was spread in every quarter; but at length the time arrived, and nothing extraordinary having been observed, it gave decidedly the lie both to the prediction and the art; but notwithstanding this, the people still continued to pay the same reverence to the science and its professors as formerly, nothing being sufficient to open the eyes of the infatuated multitude.

The Europeans having received their first notions of astronomy from the Arabians, it was to be expected that they would partake also of their superstitious belief in astrology. Indeed in all those obscure ages which preceded the regeneration of the arts, none seemed to doubt of the influence of the stars on the destiny of man, and most of those who studied or cultivated astronomy, had no other object in view, than its application to astrological predictions.

But what must be our opinion of the church of Rome, when we find one of its cardinals so much infatuated with his belief in this doctrine, that he actually drew the horoscope of Jesus Christ, from a pretended knowledge that he professed to have of the moment of his birth; and this being what may be called predicting after the event, he failed not to find written in the heavens all the circumstances of his life and death. And the manner in which he endeavoured to defend himself from the charge of impiety alleged against him was equally as ridiculous as the assertion itself.

Among the most celebrated astrologers of Europe, we find many whose works on other subjects have done honour to themselves and to their country, and it is to be wished that they had confined their labours only to these subjects. Such were Regiomontanus, Camerarius, Cardan, Argoli, Morin, Tycho Brahe, and his patron and friend count Rantzau; to these we may add, Guido

Botanus de Forli, who was the author of six treatises on Astrology; Stöffler, who published for many years an ephemeris containing astrological predictions. In his almanac for 1499, he announced for the year 1514 a terrible inundation throughout Europe, on account of the conjunction of the superior planets in the sign pisces: but this, as also a similar one by Virdungus, was, when the time arrived, most completely belied by the events, for these years were rather more dry than usual. These ephemerids were similar to our present Moore's almanac, which to the disgrace of the country still carries on this species of deception, and which, notwithstanding its many and palpable contradictions, is at this day regarded as the oracle of wisdom among the greater part of our peasantry.

But perhaps none of those above cited, except Tycho Brahe, was so enthusiastically devoted to astrology as Cardan. He even, in imitation of the Roman cardinal, attempted from the configuration of the heavens to draw the horoscope of Christ; and many other of his notions were equally absurd and ridiculous. He firmly believed in the influence of the stars on the fates and destinies of kingdoms. Thus Butler says:

"Cardan believ'd great states depend
Upon the tip o' th' bear's tail's end;
That as she whisk'd it t'wards the sun,
Strow'd mighty empires up and down."

He drew his own horoscope; and it has been said that he even starved himself, in order that the time of his death should not give the lie to his doctrine; but this is not true, for he died before the time that his stars had predicted for that event. Junctinus is another who has written largely on this subject; he was astrologer to Catharine de Medicis, at the same time that he was almoner to the duke of Anjou; and a column was erected to him in the Halle au Blé; but he died at last in indigent circumstances at Lyons; an event which he did not probably foresee notwithstanding his astrological skill. To these we may farther add the famous John Dee, who acted in the capacity of astrologer to queen Elizabeth, by whom he was consulted as to the time propitious for her coronation; and his friend and companion Kelly, another of the heroes that Butler has introduced in that character,

"Kelly did all his fates upon,
The devil's looking-glass, a stone."

From which we may conclude, that he dealt a little in the magical way, beside his more common occupation of astrology. But count Rantzau, and his ally Tycho Brahe, were perhaps the most zealous defenders of astrology; the latter having written largely in defence of the truth of this science, the tendency of which was to show its connexion with the christian religion, and the impiety in doubting of the truth of its doctrine. Even Kepler was in some measure addicted to astrology, as appears from several of his letters to his friends, where he is seriously discussing the best method of drawing an horoscope: he was not however so violent and daring as Stöffler, and Cardan; making hardy and dangerous predictions, which dishonoured both the art and artist.

Morin, who was born in 1583, was the last astrologer of any note, and whose attempts to defend the doctrine of astrology may be considered as the last efforts of this expiring art; he was an outrageous opponent to the Copernican system, with respect to the motion of the earth, and is said to have laboured 30 years at his *Astrologia Gallica*, and predicted the death of his adversary the learned Gas-

sendi, a number of times; but the latter seemed to rise from under his frequent afflictions, in order to give the lie to Morin's doctrine. He even foretold the death of Louis xiii, who never was in better health than at the time announced by Morin for his death: finally, his works and his predictions being generally contradicted by the events, they were despised and ridiculed by all his contemporaries who had any reputation in the sciences, and his favourite doctrine seemed to lose ground, as the truth of the modern system of astronomy became more generally acknowledged. That a man of this description, an astrological bigot, should so strongly combat the idea of the motion of the earth, is by no means surprising; because the old system of astronomy was much more favourable to the doctrine of astrology than the modern. Indeed it was to this system having finally prevailed over the obstacles that ignorance and superstition had raised against it, that was the principal cause of plunging astrology into that contempt it so justly merited. For as soon as it was known that the earth was not the centre of the universe; that it was only one of the little satellites of the sun; that instead of the sun and stars turning about the earth, it turned on its own axis to receive the light and heat of that luminary; and finally, that the fixed stars are placed at an immense distance, that even startles the imagination;—how could it for a moment be admitted, that all this vast machine was subordinate to this little globe of earth, and be designed only to preside over the destinies of its inhabitants!

Morin died in 1656, since which time astrology has been declining; and at this day there is not a man of science in Europe who is not fully aware of the absurdity of this pretended doctrine.

But in the East, astrology still preserves its credit; and astronomy is only cultivated there, so far as it is thought necessary for astrological purposes; for the Turks can no more be persuaded that the Europeans study astronomy without believing in astrology, than imagine that we can examine the inscriptions and ruins of antiquity, without searching for treasure.

It may be thought that too much has been said on this subject, that even its name ought not to be introduced into books of science; and certainly, were it not for the benefit that astronomy has derived from it, and the respectability of many authors who, unfortunately for their memoirs, have been its admirers and supporters, it would long before this have been lost in total oblivion, and even its name would not have been remembered by philosophers. But those circumstances cannot fail of giving it some interest when we are contemplating the progress of human knowledge, and when we reflect, that without this superstitious stimulus, we might still have remained ignorant of those grand and sublime laws, that regulate the motion of the heavenly bodies, and preserve unimpaired, the universal harmony of our planetary system.

ASTROMETI-OROLOGIA, the art of foretelling the weather, and its changes, from the aspects and configurations of the moon and planets: a species of astrology distinguished by some under the denomination of *meteorological astrology*.

ASTRONOMICAL, something relating to Astronomy. ASTRONOMICAL Calendar, Characters, Column, Horizon, Hours, Month, Quadrant, Ring-Dial, Sector, Tables, Telescope, Time, Year. See the several substantives.

ASTROFOMICAL Observations. Of these there are re-

cords, or mention, in almost all ages. It is said that the Chinese have observations for a course of many thousand years. But of these, as well as those of the Indians, we have yet had but little benefit. But the observations of most of the other ancients, as Babylonians, Greeks, &c., among which those of Hipparchus make a principal figure, are carefully preserved by Ptolemy, in his *Almagest*.

About the year 880, Albategni, a Saracen, applied himself to the making of observations; in which he was followed by others of the same nation, as well as Persians and Tartars; among whom were Nassir-Eddin-Litusi, Arzachel, who also constructed a table of sines, and Ulug Beghi. In 1457 Regiomontanus undertook the province at Nuremberg; and his disciples, J. Werner and Ber. Walther, continued the same from 1475 to 1504. Their observations were published together in 1544.—In 1509, Copernicus, and after him the landgrave of Hesse, with his assistants Rothman and Byrge, observed; and after them Tycho Brahe, assisted by the celebrated Kepler, from 1582 to 1601.—All the foregoing observations, together with Tycho's apparatus of instruments, are contained in the *Historia Cœlestis*, published in 1672, by order of the emperor Ferdinand.—In 1651, was published at Bononia, by Ricciolus, *Almagestum Novum*, being a complete body of ancient and modern observations, which he so named after the work of the same nature by Ptolemy.—Soon after, Hevelius, with a magnificent and well-contrived apparatus of instruments, described in his *Machina Cœlestis*, began a course of observations. It has been objected to him, that he only used plain sights, and could never be brought to take the advantage of telescopic ones; which occasioned Dr. Hooke to write animadversions on Hevelius's instruments, printed in 1674, in which he too rashly despises them, on account of their inaccuracy: but Dr. Halley, who at the instance of the Royal Society went over to Dantick in the year 1679, to inspect his instruments, approved of their justness, as well as of the observations made with them. See *SIGHTS*.—Our two countrymen Jer. Horrox and Will. Crabtree, are celebrated for their observations from the year 1635 to 1645, who first observed the transit of Venus over the sun in the year 1639.—They were followed by Flamsteed, Cassini the father, and son, Halley, de la Hire, Roemer, and Kirchius.—We have also now had published the accurate observations of Dr. Bradley and of Dr. Maskelyne; as also those of the French and other observatories, with the observations of many ingenious private astronomers, which are to be found in the *Transactions* and *Memoirs* of the various Philosophical Societies.—There have been also observations of many other eminent astronomers; as, Galileo, Huygens, and our countryman Marriot, whose very interesting observations have lately been brought to light by the earl of Egremont, and count Bruhl, though they have not been thought fit to be published. Other publications of celestial observations, are those of Cassini, La Caille, Monnier, Lalande, Herschel, &c.—See farther under *CELESTIAL Observations*, *CATALOGUE*, *observatory*, &c.

ASTRONOMICAL Place of a star or planet, is its longitude, or place in the ecliptic, reckoned from the beginning of aries, *in consequentia*, or according to the order of the signs.

ASTRONOMICALS, a name used by some writers for sexagesimal fractions; on account of their use in astronomical calculations.

ASTRONOMICUS Radius. See *RADIUS*.

ASTRONOMY, the doctrine of the heavens, and their phenomena. Astronomy is properly a mixed mathematical science, by which we become acquainted with the celestial bodies, their motions, periods, eclipses, magnitudes, distances, and other phenomena. Some, however, understand the term astronomy in a more extensive sense, as comprising in it the theory of the universe, with the primary laws of nature: in which sense it seems to be rather a branch of physics than of mathematics.

History of Astronomy.—The invention of astronomy has been variously given, and ascribed to several persons, several nations, and several ages. Indeed it is probable that mankind never existed without some knowledge of astronomy amongst them. For, besides the motives of mere curiosity, which are sufficient of themselves to have excited men to a contemplation of the glorious and varying celestial canopy, it is obvious that some parts of the science answer such essential purposes to mankind, as to make the cultivation of it a matter of indispensable necessity.—Accordingly we find traces of it in various nations, and records of its cultivation by the earliest inhabitants. Josephus informs us, that the sons of Seth employed themselves in the study of astronomy, and that they engraved their observations on two pillars, one of brick and the other of stone, in order that they might be preserved from the destruction which Adam had foretold should come upon the earth. He also relates that "Abraham gave lectures in astronomy and arithmetic to the Egyptians," "which," he says, "they knew nothing of, till Abraham brought them from Chaldea to Egypt, and from thence they passed to the Greeks." Berosus also observes, "that Abraham was a great and just man, and famous for his celestial observations." The same author ascribes to the antediluvians a knowledge of the astronomical cycle of 600 years, which may be supposed to mean the period in which the sun and moon came again into the same situation with regard to the nodes, apogee of the moon, &c. "This period," says Cassini, "of which we find no intimation in any monument of any other nation, is the most accurate of the kind that ever was invented: for it brings out the solar year more exactly than that of Hipparchus and Ptolemy; and the lunar month within about one second of what is determined by modern astronomers." If the antediluvians had such a period of 600 years, they must have known the motions of the sun and moon more exactly than their descendants knew them some ages after the flood.

The accounts however which we have of these matters, anterior to the flood, do not carry with them the degree of credibility that would justify a more particular mention of them; nor would a more copious detail conduct us to any certain conclusion of the age or country where the science of astronomy first originated, or by whom it was first methodised and extended. Whatever credibility these uncertain testimonies of the ancients may possess; certain it is that most authors are agreed that the commencement of the science originated either in Chaldea, Egypt, or India; all of which nations pretended to a very high antiquity, and equally claimed the honour of producing the first cultivators of this science. The Chaldeans in particular boasted of their temple, and enormous tower of Belus, which has been thought by some to have been an astronomical observatory; and no less of their famous astronomer and philosopher Zoroaster, whom they placed 500 years before the destruction of Troy. While the Egyptians, with similar ostentation, vaunted of their Col-

leges of priests, which were the depôts of every species of knowledge; and of the monument of Osymandyas, in which tradition asserts, there was a golden circle of 365 cubits in circumference, and one cubit thick, divided into 365 equal parts according to the days of the year, and containing the heliacal risings and settings of the stars for each day, &c.

It is indeed evident that both Chaldea and Egypt were countries very proper for astronomical observations, on account of the extended flatness of the country, and the purity and serenity of the air. The tower of Belus, or of Babel, being of a great height, was probably an astronomical observatory; and the lofty pyramids of Egypt, whatever they were originally designed for, might perhaps answer the same purpose; at least, they show the skill of this people in practical astronomy, as they are all placed with their four fronts exactly facing the cardinal points of the compass. For it is hardly possible, that they should have placed them in that striking position, and with such a degree of exactness, without some particular reason; and this being the case, it will follow, that they were acquainted with the correct method of drawing a meridian line, which is a matter of more difficulty than is generally supposed: it being well known that Tycho Brahe, the most able astronomer of his time, committed an error of several minutes in tracing that of the observatory of Uraniborg.

The Chaldeans certainly began to make observations soon after the confusion of languages, as appears from the observations found there on the taking of Babylon by Alexander; and probably much earlier. It hence appears that they had determined, with tolerable exactness, the length both of a periodical and synodical month. They had also discovered, that the motion of the moon was not uniform; and they even attempted to assign those parts of the orbit in which the motion is quicker or slower. We are also assured by Ptolemy that they were not unacquainted with the motion of the moon's apogee and nodes, the latter of which they supposed made a complete revolution in $6585\frac{1}{2}$ days, or a little more than 18 years, and that it contained 233 complete lunations, which period is called the Chaldean Saros. From Hipparchus, the same author also gives us several observations of lunar-eclipses made at Babylon above 720 years before Christ. And Aristotle informs us, that they had many occultations of the planets and fixed stars by the moon; a circumstance which led them to conceive that eclipses of the sun were to be attributed to the same cause. They had also no inconsiderable share in arranging the stars into constellations. Nor had even those eccentric bodies the comets escaped their observation: for both Diodorus Siculus and Appollinus Myndicus, Seneca informs us, accounted these to be permanent bodies, having stated revolutions as well as the planets, but in much more extensive orbits: although others of them were of opinion, that the comets were only meteors raised very high in the air, which, blazing for a while, disappear when the matter of which they consist is consumed or dispersed. The art of dialling was also practised among them long before the Greeks were acquainted with that science. Herodotus says, that the Greeks were made acquainted with the use of the *Pole* and *Gnomon* through the medium of the Babylonians; the latter of which seems to have been the most ancient instrument made use of in astronomy.

The Egyptians, it appears from various circumstances, Vol. I.

laid claim to nearly the same critical pretensions in the knowledge of astronomy as the Chaldeans. Herodotus ascribes their knowledge in the science to Sesostris; probably not the same whom Newton makes contemporary with Solomon, as they were acquainted with astronomy at least many hundred years before that era. We learn, from the testimony of some ancient authors, many particulars relative to the state of their knowledge in this science; such as, that they believed the figure of the earth was spherical; that the moon was eclipsed by passing through the earth's shadow, though it does not certainly appear that they had any knowledge of the true system of the universe; that they attempted to measure the magnitude of the earth and sun, though their methods of ascertaining the latter were very erroneous; and that they even pretended to foretell the appearance of comets.

Diodorus Siculus also informs us that the Egyptians discovered that the planets had sometimes a direct, and sometimes a retrograde motion, and at others were stationary: that they made the sun move in a circle inclined to the equator, and in a contrary direction to the diurnal motion. The idea of dedicating the seven days of the week to the planets, is also ascribed to the Egyptians. We are also further informed by Mr. E. Barnard, that these people discovered that the stars had an annual motion of $50'' 9'' 45''$ in a year (Phil. Trans. No. 158): and by Macrobius that the Egyptians made the planets revolve about the sun in the same order as is ascribed to them by us: but it does not appear at what time the planets were first discovered to be of a different nature from the fixed stars nor by whom. They were also acquainted, as is generally supposed, with several other branches of this science, as indeed were the Chaldeans; which will appear from the first notions they entertained of the system of the world, and the agreement which has been found among several ancient measures of the circumference of the earth.

Many other nations, it is true, have claimed the honour of the original cultivation of this science; but among the various observations of the ancients which have been transmitted to us, none appear of greater antiquity than those of the Chinese. The most remarkable of these is a conjunction of five of the planets which, according to their annals, is said to have taken place in the reign of their emperor Tcheun-hiu, about 2500 years before Christ. They also mention an eclipse of the sun, which happened in the constellation Scorpio about the year 2150 of the same era; and which is said to have proved fatal to two Chinese astronomers, of the names of Ho and Hi, who were condemned to death by the emperor Tchong-kang, on account of their omitting, through negligence and intoxication, to announce the precise time at which it arrived. And from these data, apparently well attested, several eminent astronomers have endeavoured to discover whether these events could have possibly happened about the time here mentioned; but the subject is attended with too many difficulties to afford any satisfactory result.

Most of the accounts which we have of the Chinese astronomers have come from the Jesuit missionaries. They inform us, that the Chinese were originally taught the science of astronomy by their first emperor Fo-hi, who is supposed by some to be the same with Noah. He also constructed astronomical tables, and gave the figures of the heavenly bodies. In the reign of the emperor Hoang-ti, about 2697 years before Christ, Yuchi likewise observed the pole-star and the constellations circumscribing it. He

also constructed a sphere with several fixed and moveable circles; and was the author of an instrument by which he could find the four cardinal points, without any reference to the heavens; which was probably the same as a compass. Nearly about this time the cycle of 60 years was also established, and it is asserted by F. Gaubril, that for more than a century A. C. the Chinese had discovered the obliquity of the ecliptic, with the theory of eclipses: and that they were, long before that, acquainted with the true length of the solar year, the method of observing meridian altitudes of the sun by the shadow of a gnomon, and of deducing from thence his declination, and the height of the pole. The same missionary also says, that the Chinese have yet remaining some books of astronomy, which were written about 200 years before Christ; from which it appears, that the Chinese had known the daily motion of the sun and moon, and the times of the revolutions of the planets, many years before that period.

Du Halde likewise informs us, that Tcheou-cong, the most skilful astronomer that ever China produced, lived more than a thousand years before Christ; that he passed whole nights in observing the celestial bodies, and arranging them into constellations, &c. At present, however, the state of astronomy is but very low in that country, although it be cultivated at Peking, by public authority, in like manner as in most of the capital cities of Europe.

The inhabitants of Japan, of Siam, and of the Mogul's empire, have also been acquainted with astronomy from time immemorial; and the celebrated observatory at Benares, is a monument both of the ingenuity of the people, and of their skill in that science.

According to Porphyry, astronomy must have been of very ancient standing in the east. He informs us that, when Babylon was taken by Alexander, there were brought from thence celestial observations for the space of 1903 years; which therefore must have commenced within 115 years after the flood, or within 15 years after the building of Babel.—Epigenes, according to Pliny, affirmed that the Babylonians had observations of 720 years engraven on bricks.—Again, Achilles Tatius ascribes the invention of astronomy to the Egyptians; and adds, that their knowledge of that science was engraven on pillars, and by that means transmitted to posterity.

M. Bailly, in his elaborate history of ancient and modern astronomy, endeavours to trace the origin of this science among the Chaldeans, Egyptians, Persians, Indians and Chinese, to a very early period. And thence he maintains, that it was cultivated in Egypt and Chaldea 2800 years before Christ; in Persia, 3209; in India, 3101; and in China, 2952 years before that era. He also apprehends, that astronomy had been studied even long before these distant periods, and that we are only to date its revival from thence.

In investigating the antiquity and progress of astronomy among the Indians, M. Bailly examines and compares four different sets of astronomical tables of the Indian philosophers, namely that of the Siamese, explained by M. Cassini in 1689; that brought from India by M. le Gentil of the Academy of Sciences; and two other manuscript tables, found among the papers of the late M. de Lisle; all of which he found to agree very accurately, and referring to the meridian of Benares, above mentioned. It appears that the fundamental epoch of the Indian astronomy, is a conjunction of the sun and moon, which took place at the amazing distance of 3102 years before Christ: and M.

Bailly informs us that, by our most accurate astronomical tables, such a conjunction did really happen at that time. He further observes that, at present, the Indians calculate eclipses by the mean motions of the sun and moon observed 5000 years since; and that their accuracy, with regard to the solar motion, far exceeds that of the best Grecian astronomers. They had also settled the lunar motions by computing the space through which that luminary had passed in 1,000,984 days, or a little more than 4383 years. M. Bailly also informs us, that they make use of the cycle of 19 years, the same as that ascribed by the Greeks to Meton; that their theory of the planets is much better than Ptolemy's, as they do not suppose the earth in the centre of the celestial motions, and believe that Venus and Mercury move round the sun; and that their astronomy agrees with the most modern discoveries as to the decrease of the obliquity of the ecliptic, the acceleration of the motion of the equinoctial points, &c.

In the 2d vol. of the transactions of the Royal Society of Edinburgh, is also a learned and ingenious dissertation on the astronomy of the Brahmins of India, by Mr. Professor Playfair; in which the great accuracy and high antiquity of the science, among them, is reduced to the greatest probability. It hence appears, that their tables and rules of computation have peculiar reference to an epoch, and to observations, 3 or 4 thousand years before Christ; and many other instances are there adduced, of their critical knowledge in the other mathematical sciences, employed in their precepts and calculations.

Astronomy, it seems too, was not unknown to the Americans; though in their division of time, they made use only of the solar, and not of the lunar motions. And that the Mexicans, in particular, had a strange predilection for the number 13, by means of which they regulated almost every thing: their shortest periods consisted of 13 days; their cycle of 13 months, each containing 20 days; and their century of 4 periods, of 13 years each: and this excessive veneration for the number 13, arose, according to Siguenza, from its being the number of their greater gods. And it is very remarkable, that the Abbé Clavigero asserts it as a fact, that, having discovered the excess of a few hours in the solar above the lunar year, they made use of intercalary days, to bring them to an equality, as established by Julius Caesar in the Roman Calendar; but with this difference, that, instead of one day every 4 years, they interposed 13 days every 52 years, which produces the same effect.

This science however fell into great decay with the Egyptians, and in the time of the emperor Augustus, it was entirely extinct among them.

From Chaldea and Egypt the science of astronomy passed into Phenicia, which this people applied to the purposes of navigation, steering their course by the north polar star; and hence they became masters of the sea, and of almost all the commerce in the world.

The Greeks, it is probable, derived their astronomical knowledge chiefly from the Egyptians and Phenicians, by means of several of their countrymen who visited these nations, for the purpose of learning the different sciences. Newton supposes that most of the constellations were invented about the time of the Argonautic expedition; but it is more probable that they were, at least the greater part of them, of a much older date, and derived from other nations, though clothed in fables of their own invention or application. Several of the constellations are

mentioned by Hesiod and Homer, the two most ancient writers among the Greeks, and who lived about 870 years before Christ. Their knowledge in this science, however, was greatly improved by Thales the Milesian, and other Greeks, who travelled into Egypt, and brought from thence the chief principles of the science. Thales was born about 640 years before Christ; and he, first of all among the Greeks, observed the stars, the solstices, the eclipses of the sun and moon, and predicted the same. And the same was farther cultivated and extended by his successors Anaximander, Anaximenes, and Anaxagoras; but most especially by Pythagoras, who was born 577 years before Christ, and having resided for several years in Egypt, &c, brought from thence the learning of these people, taught the same in Greece and Italy, and founded the sect of the Pythagoreans. He taught that the sun was in the centre of the universe; that the earth was round, and people had antipodes; also that the moon reflected the rays of the sun, and was inhabited like the earth; that comets were a kind of wandering stars, disappearing in the further parts of their orbits; that the white colour of the milky-way was owing to the united brightness of a great multitude of small stars; and he supposed that the distances of the moon and planets from the earth, were in certain harmonic proportions to one another.

Philolaus, a Pythagorean, who flourished about 450 years before Christ, asserted the annual motion of the earth about the sun. He was persecuted for propagating this opinion, and obliged to fly; and it is a circumstance worthy of remark, that Galileo lost his liberty for maintaining the same. Not long after, the diurnal motion of the earth on her own axis, was taught by Hicetas, a Syracusan. About the same time flourished at Athens, Meton and Euctemon, where they observed the summer solstice 432 years before Christ, and observed the risings and settings of the stars, and what seasons they answered to. Meton also invented the cycle of 19 years, which still bears his name.

The next astronomer was Eudoxus the Cnidian, and scholar of Plato, who lived about 370 years before Christ, and was accounted one of the most skilful astronomers and geometricians of antiquity, being esteemed the inventor of many of the propositions in Euclid's Elements, and having introduced geometry into the science of astronomy. He travelled into Asia, Africa, Sicily, and Italy, for improvements in astronomy; and we are informed by Pliny, that he determined the annual year to contain 365 days 6 hours, and also the periodical times of the planets, and made other important observations and discoveries.

Calippus flourished soon after Eudoxus, and his celestial sphere is mentioned by Aristotle; but he is better known by his invented period of 76, containing 4 corrected Metonic periods, and which commenced at the summer solstice in the year 330 before Christ. About his time the knowledge of the Pythagorean system was carried into Italy, Gaul, and Egypt, by certain colonies of Greeks.

However, the introduction of astronomy into Greece is represented by Vitruvius in a manner somewhat different. He maintains, that Berosus, a Babylonian, brought it immediately from Babylon itself, and opened an astronomical school in the isle of Cos. And Pliny says, that in consideration of his wonderful predictions, the Athenians erected him a statue in the gymnasium, with a gilded tongue. But if this Berosus be the same with the author of the Chaldaic histories, he must have lived before Alexander.

After the death of this conqueror, the sciences flourished chiefly in Egypt, under the auspices of Ptolemy Philadelphus and his successors. He founded a school there, which continued to be the grand seminary of learning, till the invasion of the Saracens in the year of Christ 650. From the founding of that school, the science of astronomy advanced considerably. Aristarchus, about 270 years before Christ, strenuously asserted the Pythagorean system, and gave a method of determining the sun's distance by the dichotomy of the moon.—Eratosthenes, who was born at Cyrene in the year 271 before Christ, measured the circumference of the earth by means of a gnomon; and being invited to Alexandria, from Athens, by Ptolemy Euergetes, and made keeper of the royal library there, he set up for that prince those armillary spheres, which Hipparchus and Ptolemy the astronomer afterwards employed so successfully in observing the heavens. He also determined the distance between the tropics to be $\frac{1}{5}\frac{1}{3}$ of the whole meridian circle, which makes the obliquity of the ecliptic in his time to be $23^{\circ} 51' \frac{1}{3}$.—The celebrated Archimedes likewise cultivated astronomy, as well as geometry and mechanics: he determined the distances of the planets from one another, and constructed a kind of planetarium or orrery, to represent the phenomena and motions of the heavenly bodies.

The next ancient astronomer that deserves our most grateful acknowledgements, for the number of his correct observations, as well as the important conclusions he derived from them, is Hipparchus. This celebrated astronomer was the first who cultivated all the branches of this science; his first labours were directed to the obliquity of the ecliptic, observed by Eratosthenes, which he found to be perfectly correct; and this was afterwards confirmed by Ptolemy. He next attempted to determine the length of the tropical year; a thing which had not been done by his predecessors, as he conceived, with that degree of accuracy as the importance of it deserved: this he did by observing the interval of the return of the sun to the same tropic or equinox: he imagined that if he could get two corresponding observations, after a great number of revolutions, the error would be proportionally diminished; which was the method employed by future astronomers, in determining the mean motions of all the planets; a discovery of very high importance in this science. He compared the observation of a solstice by Aristarchus, with one made by himself, at the interval of 145 years, and found that this happened half a day sooner than it ought to have done, if the year consisted of $365\frac{1}{4}$ days, as the Greeks believed before him. Thus then he determined the tropical year to be $365^d 5^h 55^m 12^s$, being nearly $4\frac{1}{2}$ minutes too great. He constructed the first solar tables, of which any mention is made in the history of astronomy; and discovered the excentricity of the sun's orbit: he also considered the motion of the moon, and attempted to estimate the exact time of her revolution, by a comparison of ancient eclipses; he likewise discovered the excentricity of her orbit, as indeed he did that of all the planets: he found that the moon's motion was not uniform, that she moved slower in the apogee of her orbit than in the perigee, and that there was a motion of anticipation of her nodes: he collected the accounts of the Egyptians and Chaldeans relative to eclipses; and calculated all that were to happen for 600 years to come. It is also to this celebrated astronomer that we are indebted for the discovery of the principle of the equa-

tion of time, and the equally important one of the precession of the equinoxes: he found that the stars changed their declinations, but not their latitudes, and on which account he referred them to the ecliptic. He also knew that an eclipse of the sun varied on different parts of the earth; and thus discovered that the moon had a parallax; and this suggested to him a method of determining the sun's distance from the earth more accurately than any of his predecessors had done; he also enriched geography with many discoveries, and was the first writer that we are acquainted with on spherical trigonometry; but his chief work is a catalogue which he made of the fixed stars, to the number of 1022, with their longitudes, latitudes, and apparent magnitudes; which, with most of his other observations, are preserved by Ptolemy in his Almagest.

After this period it may be remarked, that little progress was made in this science from the time of the last-mentioned astronomer to that of Ptolemy, who was born at Ptolemais in Egypt, in the first century of Christianity, and who made the greatest part of his observations at the celebrated school of Alexandria in that country. Profiting by those of Hipparchus, and other ancient astronomers, he formed a system of his own, which, though erroneous, was followed for many ages by all nations. He compiled a great work, called the Almagest, a name given it by the Arabs: but which was originally entitled *Mēzān al-Sūrātīs*, or Great Construction. From its containing the observations and collections of Hipparchus, Timocharis, and others his predecessors in astronomy, it will ever be valuable to the professors of that science. Thus did the Alexandrian school continue to be enriched, and to gain celebrity in science, for more than five centuries; when (as has been observed) an event the most calamitous, and the most disgraceful to its perpetrators, laid in ruins its valuable library, and consumed in one hour the labours of all the most celebrated astronomers of that period. But it deserves to be remarked, that the very people who destroyed those admirable treasures of learning and invention, became afterwards the protectors of science and literature, and cultivated astronomy with the greatest ardour.

Geography likewise is much indebted to Ptolemy for his meritorious services in collecting all the determinations of the latitudes and longitudes of places then known, and for his fundamental principle of the methods of projections for constructing geographical charts; which was scarcely known before his time. The Almagest was preserved from the lamentable conflagration of the Alexandrine library by the Saracens, and translated out of Greek into Arabic in the year 827, and thence into Latin in 1230. The Greek original was not known in Europe till the beginning of the 15th century, when it was brought from Constantinople, then taken by the Turks, by George, a monk of Trabzon, by whom it was translated into Latin; and various other editions have since appeared.

During the long period from the year 800 till the beginning of the 14th century, the western parts of Europe were involved in the utmost ignorance and barbarity, while the Arabians, profiting by the books they had preserved from the wreck of the Alexandrine library, cultivated and improved all the sciences, and particularly that of astronomy, in which they had many able professors and authors. The caliph Al Mansur first introduced a taste for the sciences into his empire. His grandson Al Mammon, who ascended the throne in 814, was a great en-

courager and improver of the sciences, and especially of astronomy. Having constructed proper instruments, he made many observations; determined the obliquity of the ecliptic to be $23^{\circ} 35'$; and under his auspices a degree of the circle of the earth was measured a second time in the plain of Singar, on the border of the Red Sea. About the same time Alferganus wrote elements of astronomy; and the science was from hence greatly cultivated by the Arabians, but principally by Albategnius, who flourished about the year 880, and who greatly reformed astronomy, by comparing his own observations with those of Ptolemy: hence he computed the motion of the sun's apogee from Ptolemy's time to his own; settled the precession of the equinoxes at one degree in 70 years; and fixed the obliquity of the ecliptic at $23^{\circ} 35'$. The tables which he composed, for the meridian of Aracta, were long esteemed by the Arabians. After his time, though the Saracens had many eminent astronomers, several centuries elapsed without producing any very valuable observations, excepting those of some eclipses observed by Ebn Younis, astronomer to the caliph of Egypt, by means of which the quantity of the moon's acceleration since that time may be determined.

Other eminent Arabian astronomers, were, Arzachel a Moor of Spain, who observed the obliquity of the ecliptic: he also improved trigonometry by constituting tables of sines, instead of chords of arches, dividing the diameter into 300 equal parts. And Alhazen, his contemporary, who wrote upon the twilight, the height of the clouds, the phenomenon of the horizontal moon, and who first showed the importance of the theory of refractions in astronomy.

Ulug Beg, grandson of the celebrated Tartar prince Tamerlane, was a great proficient in practical astronomy; he had very large instruments, particularly a quadrant of about 180 feet high, with which he made good observations. From these he determined the latitude of Samarcand, his capital, to be $39^{\circ} 37' 23''$; and composed astronomical tables for the meridian of the same so exact, that they differ very little from those constructed afterwards by Tycho Brahe; but his principal work was his Catalogue of the fixed stars, made also from his own observations in the year 1437.

During this period, almost all Europe was immersed in gross ignorance. But the settlement of the Moors in Spain introduced the sciences into Europe; from which time they have continued to improve, and to be communicated from one people to another, to the present time, when astronomy, and all the sciences, have arrived at a very eminent degree of perfection. The emperor Frederick II, about 1230, first began to encourage learning; restoring some decayed universities, and founding a new one in Vienna: he also caused the works of Aristotle, and Ptolemy's Almagest, to be translated into Latin; and from the translation of this work we may date the revival of astronomy in Europe. Two years after this, John de Sacro Bosco, that is, of Halifax, likewise compiled, from Ptolemy, Albategnius, Alferganus, and other Arabic astronomers, his work *De Sphaera*, which was held in the greatest estimation for 300 years after, and was honoured with commentaries by Clavius and other learned men. In 1240, Alphonso, king of Castile, not only cultivated astronomy himself, but greatly encouraged others; and by the assistance of several learned men he corrected the tables of Ptolemy, and composed those which were denomin-

nated from him the Alphonsine Tables. About the same time also, Roger Bacon, an English monk, wrote several tracts relative to astronomy, particularly of the lunar aspects, the solar rays, and the places of the fixed stars. And, about the year 1270, Vitello, a Polanede, composed a treatise on optics, in which he showed the use of refractions in astronomy. Also our poet Chaucer, who was born in 1328, wrote a large and learned work on the Astrolabic, as he calls it, and indeed on practical astronomy in general, detailing all the precepts very particularly and orderly.

Little other improvement was made in astronomy till the time of Purbach, who was born in 1423. He composed new tables of sines for every 10 minutes, making the radius 60, with four ciphers annexed. He constructed spheres and globes, and wrote several astronomical tracts; as, a commentary on Ptolemy's Almagest; some treatises on Arithmetic and Dialling, with tables for various climates; new tables of the fixed stars reduced to the middle of that century; and he corrected the tables of the planets, making new equations to them where the Alphonsine tables were erroneous. In his solar tables, he placed the sun's apogee in the beginning of Cancer; but retained the obliquity of the ecliptic $23^{\circ} 33' \frac{1}{2}$, as determined by the latest observations. He also observed some eclipses, made new tables for computing them, and had just finished a theory of the planets, when he died, in 1462, being only 39 years of age.

Purbach was succeeded in his astronomical and mathematical labours by his pupil and friend, John Muller, commonly called Regiomontanus, from Montereig, or Königsberg, a town of Franconia, where he was born. He completed the epitome of Ptolemy's Almagest, which Purbach had begun; and after the death of his friend, was invited to Rome, where he also made many astronomical observations. Being returned to Nuremberg in 1471, by the encouragement of a wealthy citizen named Bernard Walther, he made several instruments for astronomical observations, among which was an armillary astrolabe, like that used in Alexandria by Hipparchus and Ptolemy, with which he made many observations, using also a good clock, which was then but a late invention. He also made ephemerides for 30 years to come, showing the lunations, eclipses, &c.; and, the art of printing having then been lately invented, he printed the works of many of the most celebrated ancient astronomers. He wrote the Theory of the Planets and Comets, and a treatise on triangles, still in repute for several good theorems; computing the table of sines for every single minute, to the radius 1000000, and introducing the use of tangents also into trigonometry. After his death, which happened at Rome in 1476, being only 40 years of age, Walther collected his papers, and continued the astronomical observations till his own death also. The observations of both were collected by order of the senate of Nuremberg, and published there in 1544 by John Schoner: they were also afterwards published in 1618 by Snellius, at the end of the observations made by the Landgrave of Hesse; and lastly with those of Tycho Brahe in 1666.

Walther was succeeded, as astronomer at Nuremberg, by John Werner, a clergymen. He observed the motion of the comet in 1503; and wrote several tracts on geometry, astronomy, and geography in a masterly manner; the most remarkable of which, are those concerning the mo-

tion of the 8th sphere, or of the fixed stars: in this tract, by comparing his own observations, made in 1514, with those of Ptolemy, Alphonsus, and others; he showed that the motion of the fixed stars, since called the precession of the equinoxes, is $19^{\circ} 10'$ in 100 years. He made also the first star of Aries 26° distant from the equinoctial point, and the obliquity of the ecliptic only $23^{\circ} 28'$. He also constructed a planetarium, representing the celestial motions according to the Ptolemaic hypothesis; and published a translation of Ptolemy's Geography, with a commentary, in which he first proposed the method of finding the longitude at sea by observing the moon's distance from the fixed stars; now so successfully practised for that purpose. Werner died in 1528, at 60 years of age.

The next astronomer of eminence after the celebrated characters just mentioned, was Nicholas Copernicus, who was born at Thorn, in Prussia, January 19th, 1472. He is peculiarly deserving of notice, for having restored the old Pythagorean system of the world, which had continued to be universally neglected from the time of Ptolemy, and which is now so universally received throughout all the civilised countries of Europe. After much time spent in meditation on the various systems, and an attentive examination of all the hypotheses of his predecessors, he found that a circular motion of the planets about the earth was insufficient to solve the phenomena; and he could not admit the revolution of these bodies about an imaginary centre, which the doctrine of epicycles inculcated. He therefore sought for a happier expedient, and was soon led to the establishment of his own system, by the opinions which he found had been suggested by other astronomers. He learnt that Philolaus had placed the sun in the centre, and that Nicetas had given the earth a rotation about its axis; the previous knowledge of which was, doubtless, of the greatest utility in facilitating his laudable enquiries. The notion of placing the most glorious luminary in the heavens in the centre, could not but strike him with delight, it being so natural an idea; but, to bring it forward as the basis of a system, supported by such new and demonstrative arguments in its favour, was a circumstance of much greater moment. Speaking of its merits, he says, "By long observations, I discovered that if the motions of the planets be compared with that of the earth, and be estimated according to the times in which they perform their revolutions, not only their several appearances will follow from this hypothesis, but it will so connect the order of the planets, their orbits, magnitudes, and distances, and even the apparent motion of the fixed stars, that it will be impossible to remove one of these bodies out of its place without disordering the rest, and even the whole frame of the universe." Having formed the rudiments of his system, he applied himself with the greatest assiduity to the improvement of it, by making numerous observations, and comparing them with those of his predecessors. By these he constructed new tables, which, with the true system of the universe, were given in his great work of astronomy, entitled *Astronomia Instaurata*. But, in consequence of the dread of persecution from religious bigots, and violent opposition from others under the denomination of astronomers, the publication of this valuable performance was protracted, and the printing of it delayed till the year 1543, when Schoner and Osiander undertook the care of it, and the work came out under the title of *Revolutiones Orbium Cœlestium*,

a copy of which Copernicus received a few hours before his dissolution, which happened on the 23d of May, 1543, in the 71st year of his age.

After the death of Copernicus, the science and practice of astronomy were greatly improved by many other persons, as Schoner, Nonius, Appian, Gemma Frisius, Rothman, Byrgius, the Landgrave of Hesse, &c.—Schoner reformed and explained the calendar, improved the methods of making celestial observations, and published a treatise on cosmography; but he died four years after Copernicus.—Nonius, or Nunez, wrote several works on mathematics, astronomy and navigation, and invented some useful and more accurate instruments than formerly; one of these was the astronomical quadrant, on which he divided the degrees into minutes by a number of concentric circles; the first of which was divided into 90 equal parts or degrees, the second into 89, the third into 88, and so on, to 46; so that, the index of the quadrant always falling upon or near one of the divisions, the minutes would be known by an easy computation. Nunez wrote also a tract on the Twilight; and a neat treatise on Algebra; besides other pieces.—The chief work of Appian, the Casarean Astronomy, was published at Ingolstadt in 1540; in which he shows, how to observe the places of the stars and planets by the astrolabe; to resolve astronomical problems by certain instruments; to predict eclipses, and to describe the figures of them; and the method of dividing and using an astronomical quadrant; at the end are added observations of 5 comets, one of which has been supposed the same with that observed by Hevelius, and if so, it ought to have returned again in the year 1789;—but it was not observed then. Gemma Frisius wrote a commentary on Appian's Cosmography, accompanied with many observations of eclipses: he also invented the astronomical ring, and several other instruments, useful in taking observations at sea; and was also the first who recommended a time-keeper for determining the longitude at sea.—Rheticus gave up his professorship of mathematics at Witteinberg, that he might attend the astronomical lectures of Copernicus; and, for improving astronomical calculations, he began a very extensive work, being a table of sines, tangents, and secants, to a very large radius, and to every 10 seconds, or $\frac{1}{6}$ of a minute; which was completed by his pupil Valentine Otho, and published in 1594.

About the year 1561, William IV, Landgrave of Hesse Cassel, applied himself to the study of astronomy, having furnished himself with the best instruments that could then be made: with these he made a great number of observations, which were published by Snellius in 1618, and which were preferred by Hevelius to those of Tycho Brabé. From these observations he formed a catalogue of 400 stars, with their latitudes and longitudes, adapted to the beginning of the year 1593.

The next astronomer of note was Tycho Brabé, a noble Dane, who, from his assiduous attention to this science, became one of the greatest observers that ever existed: he began his observations about the same time with the Landgrave of Hesse, above mentioned, and observed the great conjunction of Jupiter and Saturn; but finding the usual instruments very inaccurate, he constructed many others, much larger and exacter, with which he applied himself diligently to observe the celestial phenomena. In 1571 he discovered a new star in the

chair of Cassiopeia; which induced him, like Hipparchus on a similar occasion, to make a new catalogue of the stars; which he did to the number of 777, and adapted their places to the year 1600. In the year 1576, by favour of the king of Denmark, he built his new observatory, called Uraniburg, on the small island Huenna, opposite to Copenhagen, and which he very amply furnished with many large instruments, some of them so divided as to show single minutes, and in others the arch might be read off to 10 seconds. One quadrant was divided according to the method invented by Nonius, that is, by 47 concentric circles; but most of them were divided by diagonals, a method of division invented by a Mr. Richard Chanceler, an Englishman. Tycho employed his time at Uraniburg to the best advantage, till the death of the king; when, falling into discredit, he was obliged to remove to Holstein; and he afterwards found means of introducing himself to the Emperor Rodolph, with whom he continued at Prague till the time of his death in 1601. It is well known that Tycho was the inventor of a system of astronomy, a kind of semi-Ptolemaic, which he vainly endeavoured to establish instead of the Copernican or true system. His works, however, which are very numerous, show that he was a man of great abilities; and his discoveries, together with those of Purbach and Regiomontanus, were collected and published together in 1621, by Longomontanus, the favourite disciple of Tycho.

While Tycho resided at Prague with the emperor, he prevailed on Kepler, who had formerly been his disciple and assistant at Holstein, and from his conduct and abilities had rendered himself dear to him, to leave the university of Glatz, and to come to him, which he did with his family and library in 1600; but Tycho dying in 1601, Kepler enjoyed during his life the title of mathematician to the Emperor, who ordered him to finish the tables of Tycho Brabé, which he did accordingly, and published them in 1627 under the title of Rodolphine. He died about the year 1630 at Ratisbon, where he was soliciting the arrears of his pension. From his own observations, and those of Tycho, Kepler discovered several of the true laws of nature, by which the motions of the celestial bodies are regulated. He discovered that all the planets revolved about the sun, not in circular, but in elliptical orbits, having the sun in one of the foci of the ellipse; that their motions were not equal, but varying, quicker or slower, as they were near to the sun or farther from him; but that this motion was so regulated, that the areas described by the variable line drawn from the planet to the sun, are equal in equal times, and always proportional to the times of describing them. He also discovered, by trials, that the cubes of the distances of the planets from the sun, were in the same proportion as the squares of their periodical times of revolution. By observations also on comets, he concluded that they moved in very eccentric orbits, and crossing those of the planets in all directions, but which he could not then determine. These discoveries, and many others which are to be found in his writings, but of which no traces are discoverable in the annals of antiquity, will for ever immortalize his fame, and render his history interesting to the most distant ages.

In Kepler's time there were many other good proficients in astronomy; as Edward Wright, Baron Napier, John Bayer, &c. Wright made several good meridional observations of the sun, with a quadrant of 6 feet radius, in the

years 1594, 1595, and 1596; from which he greatly improved the theory of the sun's motion, and computed more accurately his declination than any person had done before. In 1599 he published also an excellent work entitled "Certain Errors in Navigation discovered and detected," containing a method which has commonly, though erroneously, been ascribed to Mercator.—To Napier we owe some excellent theorems and improvements in spherics, besides the ever-memorable invention of logarithms, one of the most useful ever made in the art of numbering, and of the greatest use in all the other mathematical sciences.—Bayer, a German, published his *Uranometria*, being a complete celestial atlas, or the figures of all the constellations visible in Europe, with the stars marked on them, and the stars also accompanied by names, or the letters of the Greek alphabet; a contrivance by which the stars may easily be referred to with distinctness and precision.

The next astronomer, whose labours deserve to be particularly recorded, is Galileo, who was born at Florence in the year 1564. He discovered the laws by which bodies falling freely are accelerated, and meditated deeply on their motions in general. From the valuable discoveries he made in this branch of physico-mechanical sciences, Newton and Huygens were afterwards enabled to derive the most complete and satisfactory theories of the planetary motions. Being informed of the invention of the telescope, an ever-memorable instrument, and to which we are indebted for the most brilliant discoveries, and all the accuracy to which the science of astronomy has attained, he, by duly considering the principles of refraction, constructed one himself of far superior power, by which he discovered the inequalities of the moon's surface, the satellites of Jupiter, and the ring of Saturn; also spots on the sun, by which he determined the revolution of that luminary about its axis; he also found that Venus exhibited the same phases as the moon; and discovered that nebulae and the galaxy were full of small stars. He was also a warm defender of the Copernican system, for which he was cruelly persecuted by a congregation of cardinals, who made him abjure, upon his knees, in the most solemn manner, a truth which nature and his own conviction had shown to be infallible. He was afterwards imprisoned in the inquisition at Florence, where he was born; and died in the year 1642, leaving behind him many works which testify his great skill in the sciences.

The history of astronomy, about this period, also offers us many names of very respectable observers; among whom may be noticed Mercator, Manroyceus, Homelinus, and Stevin, abroad; and in England, Thomas and Leonard Digges, John Dee, Robert Flood, Harriot, &c.; the latter of whom, who had hitherto only been distinguished as an algebraist, made nearly the same discoveries as Galileo, and at as early a period, if not more so, as appears by his papers not yet printed, in the possession of the Earl of Egremont. After whom, Mr. Horrox, a young astronomer of great talents, made considerable discoveries and improvements in this science. In 1633 he discovered that the planet Venus would pass over the sun's disc on the 24th of November 1639, an event which he announced only to his friend Mr. Crabtree; and these two were the only persons in the world that observed this transit, which was also the first time it had ever been seen by human eyes. Mr. Horrox made also many other useful observations, and had even formed a new theory of the moon, taken notice of by Newton; but his early death, in the

beginning of the year 1640, put a stop to his useful and valuable labours.

The next discoveries to Kepler's and Galileo's, were those of Huygens. This celebrated genius was the first who applied pendulums to clocks, a discovery as brilliant and advantageous as ever was presented to astronomy. He was also the first who found that the singular appearances of Saturn are produced by a ring by which the planet is surrounded; and from his great assiduity in observing it, he was led to the discovery of one of its satellites. To this memorable man, also, we are indebted for some of the most useful theorems on centrifugal forces; and, had he had an idea of combining them with his enquiries into the development of curves and the laws of Kepler, Newton had certainly not been the first to announce to the world the universal law of gravitation; but these are the things in which discoveries generally consist.

Next flourished Hevelius, Burgomaster of Dantzig, who furnished an excellent observatory in his own house, where he observed the spots and phases of the moon, from which observations he compiled his *Selenographia*; and published an account of his apparatus in his work entitled *Machina Cœlestis*, a book now very scarce, as most of the copies were accidentally burnt, with the whole house and apparatus, in 1679. Hevelius died in 1688, aged 76.

About this time the celebrated Dr. Hooke invented other instruments with telescopic sights, and censured those of Hevelius, which occasioned a sharp dispute between them; to settle which, the celebrated Dr. Halley was sent over to Hevelius to examine his instruments. The two astronomers made several observations together, very much to their satisfaction, and among them was one of an occultation of Jupiter by the moon, when they determined the diameter of the latter to be 30' 33".

Before the middle of the 17th century the construction of telescopes had been greatly improved, particularly by Huygens and Fontana. The former constructed one of 123 feet, with which he long observed the moon and planets, and discovered that Saturn was encompassed with a ring. With telescopes, also, of 200 and 300 feet focus, Cassini saw five satellites of Saturn, with his zones or belts, and likewise the shadows of Jupiter's satellites passing over his body. In 1666 Azout applied a micrometer to telescopes, to measure the diameters of the planets and other small distances in the heavens; but an instrument of this kind had been invented before, by Mr. Gascoigne, though it was but little known abroad.

To obviate the difficulties of the great lengths of refracting telescopes and the aberration of the rays, it is said that Mersene first started the idea of making telescopes of reflectors, instead of lenses, in a letter to Descartes; and in 1663 James Gregory of Aberdeen showed how such a telescope might be constructed. After some time spent also by Newton, on the construction of both sorts of telescopes, he discovered the great inconvenience which arises to refractors from the different refrangibility of the rays of light, and for which he could not then find a remedy; and therefore, pursuing the other kind, in the year 1672 he presented to the Royal Society two reflectors, which were constructed with spherical speculums, as he could not procure other figures. The inconveniences, however, arising from the different refrangibility of the rays of light, have since been fully obviated by the ingenious Mr. Dollond. Towards the latter part of the 17th, and beginning of the 18th century, practical astronomy, it seems,

rather languished. But at the same time the speculative part was carried to the highest perfection by the immortal Newton in his *Principia*, and by the Astronomy of David Gregory.

Soon after this, however, great improvements of astronomical instruments began to take place, particularly in Britain. Mr. Graham, a celebrated mechanic and watchmaker, not only improved clocks and watch work, but also carried the accuracy of astronomical instruments to a surprising degree. He constructed the old 8 feet mural arch at the Royal Observatory, Greenwich, and a small equatorial sector for making observations out of the meridian; but he is chiefly to be noticed for contriving the zenith sector of 24 feet radius, and afterwards one of 12½ feet, with which Dr. Bradley discovered the aberration of the fixed stars. The reflecting telescope of Gregory and Newton was also greatly improved by Mr. Hadley, who presented a very powerful instrument of that kind to the Royal Society in 1719. The same gentleman has also immortalized his memory by the invention of the reflecting quadrant or sector, now called by his name, which he presented to the society in 1731, and which is now used so universally at sea, especially where nice observations are required. It appears, however, that an instrument similar to this in its principles had been invented by Newton; and a description with a drawing of it given by him to Dr. Halley, when he was preparing for his voyage in 1701, to discover the variation of the needle. It has also been asserted, that a Mr. Godfrey, of Philadelphia in America, made the same discovery, and the first instrument of this kind. About the middle of this century, the constructing and dividing of large astronomical instruments were carried to great perfection by Mr. John Bird; and reflecting telescopes were not less improved by Mr. Short, who also first executed the divided object-glass micrometer, which had been proposed and described by M. Louville and others. Mr. Dollond also brought refracting telescopes to the greatest perfection, by means of his aromatic glasses; and, lately, the discoveries of Herschel are owing to the amazing powers of reflectors of his own construction.

Thus the astronomical improvements in the 18th century have been chiefly owing to the foregoing inventions and improvements in the instruments, and to the establishment of regular observatories in England, France, and other parts of Europe. Roemer, a celebrated Danish astronomer, first made use of a meridional telescope; and, by observing the eclipses of Jupiter's satellites, he first discovered the progressive motion of light, concerning which he read a dissertation before the Academy of Sciences in Paris in 1675.—Mr. Flamsteed was appointed the first Astronomer Royal at Greenwich in 1675. He observed, for 44 years, all the celestial phenomena, of the sun, moon, planets, and fixed stars, of all which he gave an improved theory and tables, viz., a catalogue of 3000 stars with their places, to the year 1689; also new solar tables, and a theory of the moon according to Horrox; likewise, in Sir Jonas Moore's System of Mathematics, he gave a curious tract on the doctrine of the sphere, showing how, geometrically, to construct eclipses of the sun and moon, as well as occultations of the fixed stars by the moon. And it was on his tables that Halley's tables and Newton's theory of the moon were also constructed. Cassini, also, the first French Astronomer Royal, very

much distinguished himself, making many observations on the sun, moon, planets, and comets, and greatly improved the elements of their motions. He also erected the gnomon, and drew the celebrated meridian line in the church of Petronia at Bologna.

In 1719 Mr. Flamsteed was succeeded by Dr. Halley, as Astronomer Royal at Greenwich. The Doctor had been sent, at the early age of 21, to the island of St. Helena, to observe the southern stars, and make a catalogue of them, which was published in 1679. In 1705 he published his *Synopsis Astronomica Cometica*, in which he ventured to predict the return of a comet in 1758 or 1759. He was the first who discovered the acceleration of the moon, and he gave a very ingenious method for finding her parallax, by three observed phases of a solar eclipse. He also published, in the Philosophical Transactions, many learned papers, and among them some that were concerning the use that might be made of the next transit of Venus in determining the distance of the sun from the earth. He composed tables of the sun, moon, and all the planets, which are still in great repute; with which he compared the observations he made of the moon at Greenwich, amounting to near 1500, and noted the differences. He recommended the method of determining the longitude by the moon's distances from the sun and certain fixed stars; a method which had before been noticed, and which has since been carried into execution, more particularly at the instance of the late Astronomer Royal, Dr. Maskelyne.

About this time a dispute arose concerning the figure of the earth. Sir Isaac Newton had determined, from a consideration of the laws of gravity, and the diurnal motion of the earth, that the figure of it was an oblate spheroid, or flattened at the poles; but Cassini had determined, from the measures of Picart, that the figure was an oblong spheroid, or lengthened at the poles. To settle this dispute, it was resolved, under Lewis xv, to measure 2 degrees of the meridian; one near the equator, and the other as near the pole as possible. For this purpose, the Royal Academy of Sciences sent to Lapland Mess. Maupertuis, Clairault, Camus, and Le Monier, &c; and, on the southern expedition were sent Mess. Godin, Condamine, and Bouguer, to whom the king of Spain joined Don George Juan and Don Antonio de Ulloa. These set out in 1735, and returned at different times in 1744, 1745, and 1746; but the former party, who set out only in 1736, returned the year following, having both fulfilled their commissions. Picart's measure was also revised by Cassini and De la Caille, which, after his errors were corrected, was found to agree very well with the other two; and the results of the whole served to confirm the determination of the figure before laid down by Newton. On the southern expedition, it was found that the attraction of the great mountains of Peru had a sensible effect on the plumb-line of one of their largest instruments, deflecting it 7 or 8 seconds from the true perpendicular.

On the death of Dr. Halley, in 1742, he was succeeded by Dr. Bradley as Astronomer Royal at Greenwich. The accuracy of his observations enabled him to detect the smaller inequalities in the motions of the planets and fixed stars. The consequence of this accuracy was, the discovery of the aberration of light, the nutation of the earth's axis, and a much greater degree of perfection in the lunar tables. He also observed the places, and computed the

elements of the comets which appeared in the years 1723, 1730, 1743, and 1757. He made new and accurate tables of the motions of Jupiter's satellites; and from a multitude of observations of the luminaries, he constructed a most accurate table of refractions, with a general rule for computing them. Also, with a very large transit instrument, and a new mural quadrant of 8 feet radius, constructed by Mr. Bird in 1750, he made an immense number of observations, for settling the places of all the stars in the British catalogue, together with near 1500 places of the moon, the greater part of which he compared with Mayer's tables. Dr. Bradley died in 1762.

In the year 1760 all the learned Societies in Europe made preparations for observing the transit of Venus over the sun, which had been predicted by Dr. Halley more than 80 years before, with the use that might be made of it in determining the sun's parallax, and the distances of the planets from the sun. The same exertions were also repeated, to observe the transit in 1769, by sending observers to different parts of the world, for the more convenience in observing. From the whole, Mr. Short computed that the sun's parallax was nearly $8\frac{3}{4}$ seconds, and consequently the distance of the sun from the earth about 24114 of the earth's diameters, or 96 millions of miles.

Dr. Bradley was succeeded, in 1762, in his office of Astronomer Royal, by Mr. Bliss, Savilian professor of astronomy; who being in a declining state of health, did not long enjoy it. But, dying in 1765, was succeeded by Dr. Maskelyne, the late Astronomer Royal, who discharged the duties of that office with the greatest honour to himself, and benefit to the science. In January 1761 this gentleman was sent by the Royal Society, at a very early age, to the Island of St. Helena, to observe the transit of Venus over the sun, and the parallax of the star Sirius. The first of these objects partly failed, by clouds preventing the sight of the 2d internal contact; and the 2d also, owing to Mr. Short having suspended the plumb-line by a loop from the neck of the central pin. However, our astronomer indemnified himself by many other valuable observations: Thus, at St. Helena, he observed the tides; the horary parallaxes of the moon; and the going of a clock, to find, by comparison with its previous motion which had been observed in England, the difference of gravity at the two places: also, in going out and returning, he practised the method of finding the longitude by the lunar distances taken with a Hadley's quadrant, making out rules for the use of seamen, and taught the method to the officers on board the ship; which he afterwards explained in a letter to the secretary of the Royal Society, inserted in the Philos. Trans. for the year 1762, and still more fully afterwards, in the British Mariner's Guide, which he published in the year 1763. He returned from St. Helena in the spring of 1762, after a stay there of 10 months; and in September 1763 sailed for the island of Barbadoes, to settle the longitude of the place, and to compare Mr. Harrison's watch with the time there, when this gentleman should bring it out: another object was also to try Mr. Irwin's marine chair, which he did in his way out. While at Barbadoes, he also made many other observations; and among them, several relating to the moon's horary parallaxes, not yet published. Returning to England in the latter part of the year 1764, he was appointed in 1765 to succeed Mr. Bliss as Astronomer Royal, and immediately recommended to the Board of Longitude the lunar method

of finding the longitude, and proposed to them the project of a Nautical Almanac, to be calculated and published to facilitate that method: this they agreed to, and the first volume was published for 1767, and which continued till his death under his direction, to the great benefit of navigation and universal commerce.

A multitude of other useful writings by this gentleman are inserted in the volumes of the Philos. Trans.; and particularly, in consequence of a proposal made by him to the Royal Society, the noble project was formed of measuring very accurately the effect of some mountain on the plumb-line, in deflecting it from the perpendicular; and the mountain of Schihallien, in Scotland, having been found the most convenient in this island for the purpose, at the request of the Society he went into Scotland to conduct the business, which he performed in the most accurate manner; showing that the sun of the deflections on the two opposite sides was about $11\frac{3}{4}$ seconds of a degree; and proving, to the satisfaction of the world, the universal attraction of all matter: from the data resulting from which measures I have computed the mean density of the whole matter in the earth, and have found it to be nearly 5 times that of common water. Besides many learned and valuable papers in the Philosophical Transactions, the most assiduous exertions in the duties of the observatory, as abundantly appears by the curious and voluminous observations which he has given to the public, the world is particularly obliged to his endeavours with the Board of Longitude, for the publication of the Nautical Ephemeris, and the method of observing the longitude, by the distances of the moon and stars, now adopted by all nations, and by which the practice of navigation has been brought to the greatest perfection. Dr. Maskelyne died the 9th of February 1811, and has been succeeded in his office by Mr. John Pond.

The discoveries of Dr. Herschel form a new era in astronomy. He first, in 1781, began with observations on the periodical star in Collo Ceti, and a new method of measuring the lunar mountains, none of which he made more than half a mile in height: and, having constructed telescopes vastly more powerful than any former ones, he proceeded to other observations, concerning which he has had several papers printed in the Philosophical Transactions; as On the rotation of the planets round their axes; On the parallax of the fixed stars; Catalogues of double, triple, &c stars; On the proper motion of the sun and solar system; On the remarkable appearances of the solar regions of the planet Mars, &c, &c; and, above all, his discovery of a new primary planet, on the 13th of March 1781, which he called the Georgian planet; though at first named the planet Herschel by the French and foreign astronomers, but lately, and more generally, Uranus; by which, and its six satellites, he has greatly enlarged the bounds of the solar system, this new planet being more than twice as far from the sun as the planet Saturn.

M. Piazzi, astronomer royal at Palermo, on Jan. 1, 1801, the first day of the 19th century, discovered another planet, moving in an intermediate orbit between Mars and Jupiter. It had long been conjectured by Maclaurin, Baxter, Lambert, Bode, Zach, and others, that there was a primary planet within this space; and the discovery has answered to some of these conjectures in a very extraordinary manner. This planet is now distinguished by the name Ceres; though it would perhaps be better to call this, and all the new planets, by the names of their

respective discoverers. Another new and small planet was discovered by Dr. Olbers of Bremen, on March 28, 1802: it is called Pallas, and is distant from Mars nearly the same as Ceres, their orbits indeed intersecting each other.—Juno is also another very small planet, in the same interval, discovered by M. Harding, at Lilienthal, on Sept. 1, 1804; and is a little farther distant than Ceres and Pallas. A fourth of these small planetary bodies was discovered by Dr. Olbers the 29th of March, 1807, which is denoted by the name of Vesta. And indeed it is highly probable that, as astronomical instruments are improved, new discoveries of this kind will be made, and our system be enlarged by the discovery of planets making their excursions even beyond the orbit of the planet Uranus, or Herschel, as well as some within the orbit of Mercury.

In the labours of scientific men on physical astronomy, the most distinguished names after Newton, are Maclaurin, Clairaut, Simpson, Euler, Walmsley, Dalembert, Friesi, Lagrange, Landen, and Laplace. Simpson, in his tracts, directed his attention to the theory of the moon. He showed that the effects of such forces as are proportional to the cosine of an arc z , are explicable by means of the cosines of that arc and of its multiples; and thus determined a very important point: for, since it hence appears, that no terms enter into the equation of the moon's orbit, but what by a regular increase and decrease do, after a certain time, return to their former values; it is therefore evident that the mean motion, and the greatest quantities of the several equations, receive no change from gravity. Friesi, in his Cosmographia, applied a similar mode of reasoning to the variations in the obliquity of the ecliptic; which he thus showed to be confined within certain limits. Laplace was conducted farther: in the general movement of a system of bodies, such as is actually exemplified in nature, every thing is in motion; not only every body, but the plane or position of every orbit. The mutual actions of the planets change the positions of the planes in which they revolve; being perpetually made to depart by a small quantity, from side to side, each from that plane in which it would go on continually, if their mutual actions were to cease. The calculus of Laplace, in the first book of his Mecanique Celeste, shows that the inclinations of these orbits, in the planetary system, are stable, or that the planes of the orbits oscillate a little, to and fro, on each side of a fixed and immovable plane. This plane is shown to be one, on which, if every one of the bodies of the system be projected by a perpendicular let fall upon it, and if the mass of each body be multiplied into the area described in a given time by its projection on the said plane, the sum of all these products shall be a maximum.

The celebrated problem of the three bodies, engaged in succession the attention of many eminent philosophers. The problem is this: Having given the masses of three bodies, projected from three points given in position, with velocities given in their quantity and direction; and supposing the bodies to gravitate to one another, with forces that are as their masses directly, and the squares of their distances inversely; to find the lines described by those bodies, and their position at any given instant. Or, the problem may be rendered universal, by assuming any number of bodies above three. To resolve the problem generally, according to either of these enunciations, exceeds the powers even of the most refined analysis: but, under the condition presented by nature, much has been done by Clairaut, Dalembert, Euler, and others. Clairaut was

the first who deduced, from his solution of the problem, a complete set of lunar tables, far more accurate than any former ones. Their accuracy, however, was exceeded by another set produced by Tobias Mayer of Gottingen, and founded on a comparison of Euler's solution with correct observations. The problem of finding the longitude at sea, which was now understood to depend so much on the exactness with which the moon's place could be computed, gave much additional value to these researches, and established a very close connexion between the conclusions of theory and the art of navigation. Mayer's tables were rewarded by the Board of Longitude in England; and Euler's, at the suggestion of Turgot, by the Board of Longitude in France.

Thus the lunar theory was brought to a high degree of accuracy; the tables constructed by means of it giving the moon's place true to $\frac{1}{4}$ a minute. Yet there remained still one inequality in the moon's motion, for which the principles of gravitation seemed to afford no account; this was what is known by the name of the moon's acceleration. Various attempts were made to explain that phenomenon by Halley, and others: it was at last satisfactorily elucidated by Laplace, who thus gave the finishing touch to the theory of the moon, nearly a century after it had been propounded in the first edition of the Principia. See ACCELERATION of the Moon.

That branch of the theory of disturbing forces which relates to the action of the primary planets on one another, was successfully cultivated between 1740 and 1780. In the course of these researches, the change in the obliquity of the ecliptic came first to be perfectly recognized, and ascribed to the action of the planets, on the earth. Euler proved, independently of Friesi, that the change in this obliquity is periodical; that it is not a constant diminution, but a slow and small oscillation, never exceeding 2° altogether on both sides of a mean quantity, by which it alternately increases and diminishes in the course of periods, which are not all of the same length, but by which, in the course of ages, a compensation ultimately takes place.

Lagrange, struck with the circumstance that the calculus had never given any inequalities but such as were periodical, applied himself to the investigation of a general question, from which he found, by a method peculiar to himself, and independent of any approximation, that the inequalities produced by the mutual action of the planets, must in effect be all periodical; that such changes are confined within narrow limits; that none of the planets ever has been, nor ever can be a comet, moving in a very eccentric orbit; but that the planetary system oscillates as it were round a medium state, from which it never deviates far: that amid all the changes which arise from the mutual actions of the planets, two things remain perpetually the same, viz, the length of the greater axis of the ellipse described by the planet, and its periodical time round the sun; or, which is the same thing, the mean distance of each planet from the sun, and its mean motion, both remain constant. The plane of the orbit varies, the species of the ellipse and its eccentricity change, but never, by any means whatever, the greater axis of the ellipse, or the time of the entire revolution of the planet. The discovery of this great principle, which may be considered as the bulwark that secures the stability of our system, and excludes all access to confusion and disorder, must render the name of Lagrange for ever memorable in science, and ever revered by those who delight in the contemplation of what-

ever is excellent and sublime. After Newton's discovery of the elliptic orbits of the planets from gravitation, Lagrange's discovery of their periodical inequalities, is doubtless the noblest truth in physical astronomy; and, in respect of the doctrine of final causes, it may be regarded as the greatest of all.

Nearly allied to this truth, is the following theorem, resulting from one of Laplace's investigations: If the mass of each planet be multiplied into the square of the eccentricity of its orbit, and this product into the square root of the axis of the same orbit, the sum of all these quantities, when added together, will remain for ever the same: this sum is of a constant magnitude, which the mutual action of the planets cannot change. Hence, no one of the eccentricities can ever increase to a greater magnitude: for, as the mass of each planet is given, as well as the axis of its orbit, the square of the eccentricity in each is multiplied into a given coefficient, and the sum of all the products so formed is incapable of change. Hence, therefore, we have an ^a general property, indicating the stability of our system within narrow limits. Yet it does not follow that this permanency is necessary and unavoidable, under every possible constitution of the planetary orbits: for, if the planets did not all move the same way; if their orbits were not all nearly circular; if their eccentricities were not small; or if the law of planetary deflection were different; the permanency of the preceding quantity could not obtain. Such permanency depends on conditions which are not necessary in themselves, and is therefore an argument of design in the construction of the universe.

The subject of the tides had its true theory sketched by Newton, but was not completed till long after his time. The state of neither mechanical nor mathematical science was such in his time as would enable any one to determine the motions of a fluid, acted on by three gravitations, and having besides a rotatory motion. The dissertations of D. Bernoulli, Euler, and Maclaurin, which shared the prize with that of P. Cavalieri on the principle of vortices, were excellent: but the first man who felt himself in possession of all the principles required in this arduous investigation, was Laplace, who, in the years 1775, 1779, and 1790, communicated to the Academy of Sciences a series of memoirs on this subject, which he has united and extended in the 4th book of the *Mecanique Celeste*. See *TIDES*; as also Edinb. Review, N^o 22.—The precession of the equinoxes is another interesting subject, to which the attention of Frisi, Walmesley, Simpson, Dalembert, Landen, Milner, M. Young, and Robertson, have been successively directed.—See the articles, *COMETS*, *ECLIPSES*, *GRAVITATION*, *MOON*, *PLANETS*, *SATELLITES*, *SUN*, *SOLAR SYSTEM*, *TIDES*, and the several planets *MERCURY*, *VENUS*, &c., &c.

On the Solar System.

The most conspicuous of all the celestial bodies is the sun, that magnificent luminary occupying the centre of the system which comprehends our earth, with a variety of other primary and secondary planets, and a still greater number of comets.—The sun is a body nearly spherical, whose diameter is about 883,250 English miles, nearly 4 times the distance of the moon from the earth. Situated nearly at the centro of the system of the planets, it exerts on them all a remarkable influence: it heats them, it enlightens them, and enchains them in their elliptical orbits,

by virtue of a force varying inversely as the squares of the distances, and directly as the masses.

The sun agrees with the fixed stars in the property of emitting light continually, and in retaining constantly its relative situation, with very little variation: it is probable also that these bodies have many other properties in common. The sun is therefore considered as a fixed star comparatively near us: and from the same analogy it is inferred that the stars are possessed of gravitation, and of the other general properties of matter; they are supposed to emit heat as well as light; and it has with reason been conjectured, that they serve to cherish the inhabitants of a multitude of planetary bodies revolving about them.

The sun, like many other stars, has probably a progressive motion, which, from a comparison of the apparent motions of a great number of the stars, is supposed to be directed towards the constellation Hercules. It is beyond all question that many of the stars have motions peculiar to themselves, and it is not certain that any of them are without such motions: it is therefore highly probable that the sun may have such motion; and indeed Dr. Herschel has confirmed this conjecture by arguments that are almost demonstrative.

Besides this progressive motion, the sun is subject to a small change of place, dependent on the situations of the planetary bodies; which was long inferred from theory only, but which has been actually demonstrated by modern observations. Supposing all the planets to be in conjunction, or nearly in the same direction from the sun, the common centre of inertia of the system is then at the distance of about a diameter of the sun from his centre, or half a diameter without his surface: and since the centre of inertia of the whole system must be undisturbed by any reciprocal actions of the bodies composing it, the sun must describe an irregular orbit round this centre, his greatest distance from it being equal to his own diameter.

The sun revolves on his axis in 25 days 10 hours, with respect to the fixed stars; this axis is directed towards a point about half way between the pole-star and Lyra, the plane of the rotation being inclined a little more than 7 degrees to the plane of the ecliptic. The direction of this motion is from west to east; and all the rotations of the different bodies which compose the solar system, as far as they have been ascertained, are in the same direction.

The time, and direction of the sun's rotation is ascertained by the change in the situation of the spots, which are often visible on his disc; and which some astronomers suppose to be elevations, but others, apparently with better reason, to be excavations or deficiencies in the luminous matter covering the sun's surface. These points are often observed to appear and disappear, and they are in the mean time liable to great variations; but they are generally found about the middle parts of the sun's surface. Lalande imagined that they were parts of the solid body of the sun, which by some agitations of the luminous ocean, with which he conceived the sun to be surrounded, are left nearly or entirely bare. Dr. Wilson and Dr. Herschel are disposed to consider this ocean as consisting, rather of a flame, than of a liquid substance; and Dr. Herschel attributes the spots to the emission of an aërial fluid, not yet in combustion, which displaces the general luminous atmosphere, and which is afterward to serve as fuel for supporting the process: hence he supposes the appearance of copious spots to be indicative of the approach of warm

seasons on the surface of the earth, and he has attempted to maintain this opinion by historical evidence. Whatever be the cause of these spots, by their often continuing during the whole time of the rotation, they have given occasion, by observations, to determine the duration of that period, as above mentioned.

The planetary system comprises at least 30 bodies, without including comets. Among these 30 bodies, the sun is the only one which is really phosphoric, or that shines with a lustre which is, properly speaking, its own. All the others are opaque; that is, they intercept the luminous fluid, and are only visible by the reflected light. 11 of these bear the name of primary planets; the other 18 are known under that of satellites or secondary planets.

The planets perform their revolutions about the sun in elliptical curves, differing but little from circles, and of which the centre of the sun (or rather the common centre of inertia of the whole system) occupies one of the foci. Commencing with that which is nearest the sun, they have the following disposition: Mercury, Venus, Terra or the Earth, Mars, Ceres or Piazzi, Pallas or Olbers¹, Juno or Harding, Vesta or Olbers², Jupiter, Saturn, and Uranus or Herschel. See plate 31.

Each of the planetary orbits is in a plane which passes through the sun's centre. The earth's orbit is named the ecliptic; which is conceived as indefinitely prolonged on all sides; and astronomers observe the situations of the planes of the other orbits by referring them to this.

All the planets move in their orbits from west to east, perform their revolutions each in equal times, and in an orbit always at the same mean distance from the sun. The velocities in their orbits are variable, being quicker in the parts nearer the sun, and proportionally slower when farther off, in such sort that equal areas are described by the radius vector, or line connecting the sun and the planet in its motion.

Mercury and Venus are nearer the sun than the earth is; on which account they are called inferior or interior planets. Those which are farther from the sun than the earth, are called superior or exterior planets.

The inferior planets can never be in opposition to the sun (see *OPOPOSITION*); but they will be found twice in conjunction with that luminary during the course of their sidereal revolution: first, when they come between the sun and the earth, making the inferior conjunction; and again, when the sun is between the planet and the earth, making the superior conjunction. See *CONJUNCTION*.

The inferior planets present different phases, when they are viewed with telescopes: these appearances are more perceptible for Venus than for Mercury, and they depend on the proper motion of those planets. If this motion be combined with that of the earth in its orbit, which is effected more slowly by reason of its greater distance from the sun, new appearances will arise, such as the direct motion of those planets in the inferior conjunction, and their retrograde motion in the superior conjunction. See *REGROGRADE*.

The orbits of the superior planets are above or include that of the earth; at the same time that the velocity of the earth is greater than those of the superior planets. Hence it results that the earth, in its motion, passes between these planets and the sun; which causes them to appear in opposition to that luminary. In the opposition they have a motion apparently retrograde; but it is direct

in the conjunction, as that of Venus and Mercury is in their superior conjunctions.

Some of the planets, as the Earth, Jupiter, Saturn, and Uranus, have satellites or moons, which revolve round those primaries, as these do about the sun. Thus, the earth has 1 moon or satellite, Jupiter 4, Saturn 7, and Uranus 6. See *Moon and SATELLITES*.

With respect to these satellites or secondary planets, the following remarkable circumstance takes place. Our moon, with the 4 satellites of Jupiter, and 1 of Saturn's, are found by observation to turn about an axis, in the same time as they respectively revolve about their primaries. And though it has not yet been ascertained from observations whether the same be true for the other satellites of Saturn, and those of Uranus; yet, from the uniformity which obviously pervades the system, it is concluded that the same is true for all the secondaries.

The planet Saturn is encompassed with a thin flat ring, or, as it is now found, with two rings, lying one within the other edgewise towards the planet, and detached from it, having their planes passing through the centre of Saturn. If a circular annulus be cut out of a card, and divided into two parts by a concentric circle, leaving the inner breadth about 3 times that of the outer; and a ball be then put within, of such a size, that the space between the ball and the annulus may be a little larger than the breadth of the annulus, a representation will thus be obtained of Saturn and his two rings. That side next the sun is bright, like the body of the planet. The rings revolve in their own plane; and, not being of a regular figure, their centre of inertia is at a small distance from the centre of Saturn. M. Laplace computed the time of their rotation to be 10^h 33^m 36^s; nearly agreeing with the time found by Dr. Herschel from observation.

If the mean distances, either of the planets or of their satellites, be compared with the duration of their sidereal revolutions, it will be easy to trace the beautiful relation discovered by Kepler; namely, that while several bodies turn about the same point, the squares of the periodical times are respectively as the cubes of their mean distances from that point: and, by combining this law with the theory of Huygens, viz, that when the squares of the periodical times, of several bodies circulating about the same point, are respectively as the cubes of the distances from that point, the central forces which animate them, are in the inverse ratio of the squares of the same distances; it will be easy to discover the law of gravitation; and, as it were, to unveil the mechanism of the planetary system.

The following tables exhibit a brief view of the solar system, according to the latest and correct account.

I. Duration of the Sidereal Revolutions of the Planets, or of their Periodic Times.

Mercury	- - - - -	87'969255	days.
Venus	- - - - -	224'700817	
The Earth	- - - - -	365'256384	
Mars	- - - - -	686'979579	
Ceres, or Piazzi	- - - - -	1680'000000	
Pallas, or Olbers ¹	- - - - -	1681'000000	
Juno, or Harding	- - - - -	2007'500000	
Ditto, by Burckhardt	- - - - -	1582'000000	
Vesta, or Olbers ²	- - - - -		
Jupiter	- - - - -	4332'602208	
Saturn	- - - - -	10759'077213	
Uranus, or Herschel	- - - - -	30689'000000	

H. *Greater Semiaxes of the Planetary Orbits, or their Mean Distances from the Sun, that of the Earth (which is about 95 millions of miles) being denoted by unity.*

Mercury	- - - - -	0'387100
Venus	- - - - -	0'723332
The Earth	- - - - -	1'000000
Mars	- - - - -	1'523693
Ceres	- - - - -	2'776755
Pallas	- - - - -	2'776909
Juno	- - - - -	2'876731
Ditto, by Burckhardt	- - - - -	2'657000
Jupiter	- - - - -	5'202778
Saturn	- - - - -	9'538785
Uranus	- - - - -	19'183475

III. Relations of Excentricity to the Greater Semiaxis I.

Mercury	(for 1750)	- - - 0'205513
Venus	ditto	- - - 0'006885
The Earth	ditto	- - - 0'016814
Mars	ditto	- - - 0'093088
Ceres	(for 1805)	- - - 0'790000
Pallas	ditto	- - - 0'246300
Juno	ditto	- - - 0'250000
Jupiter	(for 1750)	- - - 0'048077
Saturn	ditto	- - - 0'056223
Uranus	ditto	- - - 0'046683

IV. Inclination of Orbits to the Ecliptic.

Mercury	(for 1750)	- - - 7'0000
Venus	ditto	- - - 3'3930
The Earth	ditto	- - - 0'0000
Mars	ditto	- - - 1'8501
Ceres	(for 1805)	- - - 10'6167
Pallas	ditto	- - - 33'7500
Juno	ditto	- - - 21'0000
Jupiter	(for 1750)	- - - 1'3172
Saturn	ditto	- - - 2'4986
Uranus	ditto	- - - 0'7706

V. Diameters of the Planets, that of the Earth (7914 English miles) being assumed as Unity.

Mercury	- - - $\frac{2}{7}$	Jupiter	- - - $11\frac{1}{2}$
Venus	- - - $\frac{3}{4}$	Saturn	- - - $10\frac{1}{19}$
The Earth	- - - 1	His Ring	- - - $23\frac{1}{2}$
Mars	- - - $\frac{2}{3}$	Uranus	- - - $3\frac{4}{7}$
Ceres	- - - $\frac{19}{28}$	The Moon	- - - $\frac{2}{7}$
Pallas	- - - $\frac{10}{17}$	The Sun	- - - $112\frac{1}{2}$
Juno	- - - $\frac{1}{3}\frac{1}{2}$		

VI. Rotations of the Planets.

	d	h	m
Mercury	- - - - -	unknown	
Venus	- - - - -	0 23 20	
The Earth	- - - - -	0 23 56 $\frac{1}{3}$	
The Moon	- - - - -	27 7 43 $\frac{1}{2}$	
Mars	- - - - -	0 24 40	
Jupiter	- - - - -	0 9 56	
Saturn	- - - - -	0 10 17	
Uranus	- - - - -	unknown	
The Sun	- - - - -	25 10 0	

The masses of the planets have been found from principles as follow: The forces that urge two bodies, moving circularly, are in a ratio composed of the masses, the distances from the centre, and the inverse square of the periodic times (see CENTRAL FORCES); whence it results, that the gravity of one of the satellites towards its planet, is to that of the earth towards the sun, as the mean distance of the satellite from the centre of its planet, divided by the square of its periodic time, is to the mean distance

of the earth from the sun, divided by the square of its periodic time: or, expressing these gravitating tendencies by G, g , the mean distances by r, R , the periodic times by t, T , it is $G : g :: \frac{R^3}{T^2} : \frac{r^3}{t^2}$. But, denoting by M the mass of the sun, and by m , that of the planet about which the satellite revolves, by the nature of gravitation it is $G : g :: \frac{M}{R^2} : \frac{m}{r^2}$; therefore $\frac{R}{r} : \frac{T}{t} :: \frac{M}{R^2} : \frac{m}{r^2}$; consequently $\frac{R^3}{T^2} : \frac{r^3}{t^2} :: M : m$.

By applying this result to the planets which have satellites, it is easy to find the value of their masses; for, we know the radii of the orbits of the satellites, as well as the length of their sidereal revolutions, or their periodic times. Therefore, taking the cubes of the radii of these orbits, and dividing them successively by the squares of the periodic times, the quotients will give the values of the masses of the bodies, about which the satellites revolve.

As to the planets which have not satellites, Laplace has deduced the values of the masses of Venus and Mars, from the secular diminution of the obliquity of the ecliptic, and the acceleration of the moon's mean motion. The mass of Mercury was inferred from its volume, supposing the densities of that planet and the earth reciprocally as their mean distances from the sun. Mecanique Celeste, tom. 3, p. 64. Exposition du Système du Monde, ed. 2, p. 193. Thus was deduced the following table.

VII. Masses of the Planets, that of the Sun being taken for Unity.

Mercury	- - - - -	$\frac{1}{2025810}$
Venus	- - - - -	$\frac{1}{383130}$
The Earth	- - - - -	$\frac{1}{329620}$
Mars	- - - - -	$\frac{1}{1846082}$
Jupiter	- - - - -	$\frac{1}{1067}$
Saturn	- - - - -	$\frac{1}{3839}$
Uranus	- - - - -	$\frac{1}{19504}$
The Moon	- - - - -	$\frac{1}{2257890}$

The densities of bodies being in the direct ratio of their masses, and the inverse ratio of the volumes; and in bodies nearly spherical, the volumes being as the cubes of their radii; it results that the densities are then as the masses divided by the cubes of the radii. By this process the following numbers are found for the mean densities of the planets, that of the sun being assumed as unity; viz,

	to the sun 1.	to water 1.
Mercury	- - - - -	10'1743
Venus	- - - - -	5'0446
The Earth	- - - - -	3'3933
Mars	- - - - -	2'6734
Jupiter	- - - - -	0'8601
Saturn	- - - - -	0'4951
Uranus	- - - - -	0'1376
The Moon	- - - - -	2'4656
The Sun	- - - - -	1'0000

Where the first column of numbers denotes the proportion of the densities of the planets to the sun considered as unity. Then multiplying these by $1'2692 = \frac{5}{3'9392}$, we

obtain the last column of numbers, denoting the densities of the planets in respect of that of water 1. See my Tracts, vol. 2, p. 64, 66.

Besides the bodies which revolve completely round the sun, within the limits of our observation, there are others, of which we only conclude from analogy that they perform such revolutions. These are the comets; they generally appear attended by a nebulous light, either surrounding them as a coma, or stretched out to a considerable length as a tail; and they sometimes seem to consist of such light only. Their orbits are so eccentric, that in their remoter situations the comets are no longer visible to us, though at other times they approach much nearer to the sun than any of the planets; for the comet of 1680, when at its perihelion, was at the distance of only $\frac{1}{6}$ of the sun's diameter from his surface. Their tails are often of great extent, appearing as a faint light, directed always nearly opposite to the sun. It is quite uncertain of what substance they consist; and it is difficult to determine which of the conjectures concerning them is the least improbable. For further particulars, see COMET.

Lists and historical accounts of the principal writings and authors on astronomy are contained in Weidler's History of Astronomy, which is brought down to the year 1737. There is also Bailly's excellent History of astronomy, ancient and modern. For this purpose, consult also the following authors, viz. Adam, Vossius, Bayle, Chauffepié, Costard, Perraut, the chronological table of Riccioli, and that of Sherburn, at the end of his edition of Manilius; also the first volume of Lalande's astronomy. The more modern, and popular books on elementary astronomy, are very numerous, and well known: as those of Ferguson, Long, Emerson, Vince, Leadbetter, Brent, Keil, Whiston, Wing, Street, Gregory, &c., &c.

ASTROSCOPE, a kind of astronomical instrument, composed of two cones, on the surface of which are delineated the constellations, with their stars, by means of which these may easily be known in the heavens. The astroscope was invented by William Shukhard, professor of mathematics at Tubingen, on which he published a treatise in 1698.

ASTROSCOPIA, the art of observing and examining the stars, by means of telescopes, and other instruments, to discover their nature and properties.

ASTROTHEMATA, the places or positions of the stars, in an astrological scheme of the heavens.

ASTROTHESIA, is used by some for a constellation or collection of stars in the heavens.

ASTRUM, or ASTRON, a constellation, or assemblage of stars; in which sense it is distinguished from Aster, which denotes a single star. Some apply the term, in a more particular sense, to Sirius the Great Dog, or rather to the large bright star in his mouth.

ASYMMETRY, the want of proportion, otherwise called Incommensurability, or the relation of two quantities which have no common measure; as between 1 and $\sqrt{2}$, or the side and diagonal of a square.

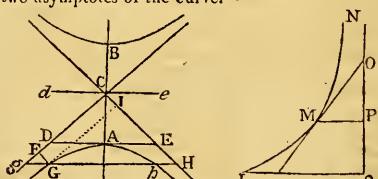

ASYMPTOTE, is properly a right line, which approaches continually nearer and nearer to some curve, whose asymptote it is said to be, in such a manner, that when they are both indefinitely produced, they are nearer together than by any assignable finite distance; or it may be considered as a tangent to the curve, when conceived to be produced to an infinite distance. Two curves are also said to be asymptotical, when they thus continually approach inde-

finitely to a coincidence: thus, two parabolas, placed with their axes in the same right line, are asymptotes to each other.

Of lines of the second kind, or curves of the first kind, viz. the conic sections, only the hyperbola has asymptotes, which are two in number. All curves of the second kind have at least one asymptote; but they may have three. Those of the third kind may have 4 asymptotes, those of the fourth kind 5; and so on for every order of curves whatever; viz, that they have as many asymptotes as the equations expressing them have dimensions, and no more. The conchoid, cissoid, and logarithmic curve, though not reputed geometrical curves, have each one asymptote. And the branch or leg of a curve that has an asymptote, is said to be of the hyperbolic kind.

The nature of asymptotes will be easily conceived from the instance of that of the conchoid. Thus, if ABC &c be part of a conchoid, and the line MN be so drawn, that the parts P, B, G, & D, M, F, C, & E, of right lines, drawn from the pole R, to the curve BCD, be equal to each other; then will the line MN be the asymptote of the curve: because the perpendicular cc is shorter than PB, and PD than CC, &c; so that the two lines continually approach; yet the points &c can never coincide.

ASYMPTOTES of the HYPERBOLA are thus described. Suppose a right line DE drawn to touch the curve in any point A, and equal to the conjugate de of the diameter AC drawn to that point A, viz. AD or AE equal to the semiconjugate cd or ce; then the two lines CDF, CEH, drawn from the centre C, through the points D and E, are the two asymptotes of the curve.

The parts of any right line, lying between the curve of the common hyperbola and its asymptotes, are equal to one another on both sides, that is, $gc = hf$. In like manner, in hyperbolas of the second kind, if there be drawn any right line cutting both the curve and its three asymptotes in three points, the sum of the two parts of that right line extended in the same direction from any two of the asymptotes to two points of the curve, is equal to the third part which extends in the contrary direction from the third asymptote to the third point of the curve.

If AGK be an hyperbola of any kind, whose nature, with regard to the curve and asymptote, is expressed by this general equation $x^m y^n = a \times x^{m+n}$, where $x = cf$, and $y = fg$ drawn any where parallel to the other asymptote CH; and the parallelogram CGE1 be completed: Then $m - n$ is to n , as this parallelogram CGE1 is to the hyperbolic space FGK, contained under the determinate line FG, with the asymptote FK and the curve GK, both indefinitely continued towards K. So that, if m be greater than n , the said asymptotic space is finite and quadrable: but when $m = n$, as in the common or conic hyperbola, then $m - n$

= 0, the ratio of that space to the said parallelogram, is as n to 0: that is, the hyperbolic space is infinitely great, in respect of the finite parallelogram: and when m is less than n , then, $m - n$ being negative, the asymptotic space is to the determinate parallelogram, as a positive number is to a negative one, and is what Dr. Wallis calls more than infinite.

ASYMPTOTE of the LOGARITHMIC CURVE. If LMN be the logarithmic curve, QON an asymptote, LQ and MP ordinates, MO a tangent, and PO the subtangent, which in this curve is a constant quantity. Then the indeterminate space $LNNQ$ is equal to $LQ \times PO$, the rectangle under the ordinate LQ and the constant subtangent PO ; and the solid generated by the rotation of that curve space about the asymptote NQ , is equal to half the cylinder, whose altitude is the said constant subtangent PO , and the radius of its base is LQ .

ASYMPTOTES, by some mathematicians, are distinguished into various orders. The asymptote is said to be of the first order, when it coincides with the base of the curvilinear figure: of the 2d order, when it is a right line parallel to the base: of the 3d order, when it is a right line oblique to the base: of the 4th order, when it is the common parabola, having its axis perpendicular to the base: and, in general, of the $n + 2$ order, when it is a parabola whose ordinate is always as the n power of the base. The asymptote is oblique to the base, when the ratio of the first fluxion of the ordinate to the fluxion of the base, approaches to an assignable ratio, as its limit; but it is parallel to the base, or coincides with it, when this limit is not assignable.

The doctrine and determination of the asymptotes of curves, is a curious part of the higher geometry. Fontenelle has given several theorems relating to this subject, in his *Geometrie de l'Infini*. See also Stirling's *Linea Tertia Ordinis*, prop. vi, where the subject of asymptotes is learnedly treated; and Cramer's *Introduction à l'analyse des lignes courbes*, art. 147 & seq., for an excellent theory of asymptotes of geometrical curves and their branches. Likewise Maclaurin's Algebra and his Fluxions, book i, chap. 10, where he has carefully avoided the modern paradoxes concerning infinites and infinitesimals. But the easiest way of determining asymptotes, it seems, is by considering them as tangents to the curves at an infinite distance from the beginning of the absciss: that is, when the absciss x is infinite in the equation of the curve, and in the proportion of \dot{x} to \dot{y} , or in that of the subtangent to the ordinate.

The areas bounded by curves and their asymptotes, though indefinitely extended, have sometimes limits to which they may approach indefinitely near: and this happens in hyperbolas of all kinds, except the first or Apollonian, and in the logarithmic curve; as was observed above. But in the common hyperbola, and many other curves, the asymptotical area has no such limit, but is infinitely great.—Solids, too, generated by hyperbolic areas, revolving about their asymptotes, have sometimes their limits; and sometimes they may be produced till they exceed any given solid.—Also the surface of such solid, when supposed to be infinitely produced, is either finite or infinite, according as the area of the generating figure is finite or infinite.

ATLANTIDES, a name given to the Pleiades, or seven stars, sometimes also called Vergiliæ. They were thus called, as being supposed by the poets to have been the

daughters either of Atlas or his brother Hesperus, who were translated to heaven.

ATMOSPHERE, is that invisible elastic fluid which surrounds the earth to an unknown height, and partakes of all its motions.—It received its name from the Greeks, in consequence of the vapours which are continually mixing with it.

Neither the properties nor the composition of the atmosphere seem to have occupied much of the attention of the ancients. Aristotle considered it as one of the four elements, situated between the regions of water and fire, and mingled with two exhalations, the dry and the moist; the former of which he considered the cause of thunder, lightning, and wind; while the second produced rain, hail, and snow. The ancients in general seemed to have considered the blue colour of the sky as essential to the atmosphere; and several of their philosophers believed that air was the constituent principle of other bodies, or at least that air and other bodies are mutually convertible into each other. But these opinions floated merely in a state of vague conjecture, till the matter was explained by the sagacity of Hales, and of those philosophers who followed the career that he had opened to them.

It was not till the time of Lord Bacon, who first taught mankind to investigate natural phenomena correctly, that the nature of the atmosphere began to be elucidated with precision. Galileo introduced the study, by showing that the air had heaviness, a point which was soon after investigated completely by his pupil Torricelli, Pascal, &c. Many other of its mechanical properties were afterwards discovered by Boyle, Mariotte, Hooke, Newton, Derham, &c; but as these belong to the subject of Pneumatics, a more particular mention of them shall be made in the articles which they respectively constitute.

The opinions of the ancient chemists, concerning the component parts of the atmosphere, are too vague to merit any particular notice. Boyle however, and his contemporaries, put it beyond doubt, that the atmosphere contained two distinct substances, viz, an elastic fluid distinguished by the name of air; and water in the state of vapour. Besides these two bodies, it was supposed also that the atmosphere contained a great variety of other substances, which were continually mixing with it, from the earth, and which often altered its properties, and rendered it noxious or fatal. Since the discovery however of carbonic acid gas, by Dr. Black, it has been ascertained that this elastic fluid always constitutes a part of the atmosphere. The constituent parts of the atmosphere, therefore, are,—1. air; 2. water; 3. carbonic acid gas; 4. unknown bodies.

That part of the composition of the atmosphere called air, has not till very lately been perfectly recognised: it seems to have been used at first to denote the atmosphere in general, and was considered for many ages merely as a simple, homogeneous, and elementary fluid; but philosophers afterwards restricted it to the elastic fluid which constitutes the greatest and most important part of the atmosphere, excluding water and other foreign bodies, which are occasionally found mixed with it. For many years, all permanently elastic fluids were considered as air, from whatever combinations they were extricated, and supposed to possess exactly the same properties as the air of the atmosphere; and it was not till the discoveries of Cavendish and Priestley had determined the peculiar properties of a

variety of elastic fluids, that philosophers became sensible that there existed various species of them. In consequence of this discovery, the word air became generic, and was applied by Priestley, and the British and Swedish philosophers in general, to all permanently elastic fluids; while the air of the atmosphere was distinguished by the epithets of common or atmospheric air; but Macquer thought proper to apply the term gas to all permanently elastic fluids except common or atmospheric air, and to confine the term air to this last fluid, an acceptance of the word which is now universally adopted by all philosophers: the word air therefore now denotes common or atmospheric air, and all other permanently elastic fluids are denominated gases.

For the knowledge of the component parts of air, we are indebted to the labours of those philosophers in whose hands chemistry advanced with such rapidity, during the last 40 years of the 18th century. The first step was made by Dr. Priestley in 1774, by the discovery of oxygen gas. This gas, according to the prevailing notions of the time, he considered as air totally deprived of phlogiston. Hence he considered common air as oxygen gas combined with an indefinite portion of phlogiston, varying in purity according to that portion; being also the purer the smaller the quantity of phlogiston it contained. Scheele also analysed the air, and found, from a process distinct from Priestley, that it was composed of two different elastic fluids, similar to those discovered by Priestley: the oxygen gas of Priestley he called empyreal air, and azotic gas he denominated foul air. Lavoisier was also conducted to the same conclusion by another different process; and thus was atmospheric air confirmed to be a compound of oxygen and azotic gas.

This point being established, it next became a question of considerable consequence to determine the proportion of these two ingredients in any given bulk of air, and to ascertain whether that proportion is in every case the same: accordingly the most eminent philosophers engaged themselves in this determination. Mr. Cavendish, by improving the eudiometer employed by Priestley and Fontana, was enabled to ascertain correctly the constituents of air (See EUDIOMETER): he found that, by mixing together oxygen gas and azote in various proportions, he should at last be able to determine the absolute quantity of oxygen in air: for since azotic gas, one of the component parts of that fluid, cannot be separated by any substance with which chemists are acquainted; the analysis of air can only be attempted by exposing it to the action of those bodies which have the property of absorbing its oxygen. By these bodies, the oxygen gas is separated, and the azote left behind, and the proportion of oxygen may be ascertained by the diminution of bulk; which being once known, it is easy to ascertain the proportion of azotic gas, and thus to determine the relative quantity of the component parts of air. Therefore, to find the absolute quantity of oxygen in air, he mixed together oxygen gas and azote in various proportions, and at last found that a mixture of 5 measures of the purest oxygen which he could procure, with 19 measures of azote, was just as much diminished by nitrous gas, as the same bulk of atmospheric air. Hence he concluded that air is composed of 5 parts of oxygen and 19 of azote, of every 24 measures of atmospheric air; which gives for its composition per cent. 7.946 azote, and 20.84 of oxygen; or very nearly 21 per cent. of oxygen gas. The trials made by others, to discover the true quantity of oxygen in air,

have all ended in the same result as that obtained by Mr. Cavendish, whenever the experiment was made with precision. They all indicate that common air consists very nearly of 21 parts of oxygen, and 79 of azote; and prove that in whatever place or altitude, above the surface of the earth, the experiment is made, the same proportion of its constituents is always manifested, let the state of the atmosphere be what it may. Gay Lussac examined air brought from an altitude of 6000 feet in a balloon, and found its constituents precisely the same as the air at the earth's surface.

The next ingredient in the composition of the atmosphere, which claims our particular notice, is water; for since it is now fully confirmed that the atmosphere always contains some portion of this fluid, it deserves to be explained in what state this comparatively heavier fluid exists in the air, and the quantity which a given bulk of the atmosphere contains precisely, if possible, made known. With respect to the state in which water exists in air, two opinions have been formed, each of which has been supported by the most eminent philosophers. 1. Water may be dissolved in air in the same manner as a salt is held in solution by water. 2. It may be mixed with air in the state of steam or vapour, after having been converted into vapour. The first of these opinions was hinted at by Dr. Hooke, in his Micrographia, and afterwards proposed by Dr. Halley; but it was much more developed by M. Le Roy, of Montpelier, in 1751. Dr. Hamilton of Dublin also made known the same discoveries about the same time. The phenomena in general coincide remarkably well with this theory. The quantity of water which air is capable of holding in solution, is increased by every augmentation of temperature, and diminished by cold, which is precisely analogous to almost all other solvents. These analogies, and several others which will easily suggest themselves to the reader, have induced by far the greater number of philosophers to adopt this opinion.

The second theory, namely that water exists in a state of vapour, is strongly confirmed by the experiments of Saussure, and the reasoning of Dr. Black; but it is to Mr. Dalton that we are indebted for the most precise information on this subject, and the perfect establishment of its reality. He demonstrated that the water existing in air possesses precisely the same degree of elasticity that it does when in the state of vapour, in a vacuum, at the same temperature; from which it follows irresistibly that it exists in air not in the state of water, but of an elastic fluid or vapour.

The first who attained any thing like precision, in attempting to measure the quantity of water in the atmosphere, was Saussure. This ingenious philosopher has shown in his Hygrometrical Essays, that an English cubic foot of air, when saturated with water, at the temperature of 66°, contains only about 8 grains troy of that liquid, or about $\frac{1}{7}$ th of its weight. But the experiments of Mr. Dalton were susceptible of far greater precision, and reflect much credit on his talents as a philosopher. His results are these:—1. That the quantity of vapour in the atmosphere is variable. 2. That in the torrid zone its force of elasticity varies from 0.6 to one inch of mercury. 3. That in Britain it seldom amounts to 0.6, but is often as great as 0.5 during summer. 4. That in winter it is frequently as low as 0.4 of an inch of mercury. From these facts, the absolute quantity of water contained in the atmosphere, at any given

time, might be correctly ascertained, provided we were certain that the density and elasticity of vapours follow the same law as that of gases, as is extremely likely to be the case. If so, the vapour will vary from $\frac{1}{6}$ th to $\frac{1}{3}$ rd part of the atmosphere. Dalton supposes that the medium quantity of vapour held in solution at once in the atmosphere, may amount to about $\frac{1}{5}$ th of its bulk. See Manchester Memoirs, vol. 3.

With regard to the next constituent part of the atmosphere, carbonic acid gas, it will be first proper to remark, that its existence was first determined by Dr. Black, immediately after he had ascertained the nature of that peculiar fluid. The exposure of a pure alkali, or alkaline earth, to the atmosphere, having been observed to be the cause of a gradual conversion of it into a carbonate, by the absorption of carbonic acid gas, rendered unavoidable the inference (as soon as the difference between a pure alkali and its carbonate had been ascertained to depend upon that acid) that carbonic acid gas existed in the atmosphere. This fact has not only been proved for the atmosphere near the surface of the earth, but established for the greatest heights accessible to man. Saussure found it at the top of Mount Blanc, the highest point of the old continent; which is covered with eternal snow, and not exposed to the influence of vegetables or animals. Humboldt has more lately ascertained the existence of this gas in air brought by M. Garnerin, from an aerial excursion into the atmosphere not less than 4280 feet above the surface of the earth; which is a fact sufficient to prove that the presence of carbonic acid in air does not depend on its vicinity to the earth.

The difficulty of separating this gas from air, has rendered it no easy matter to determine, with accuracy, the relative quantity of it in a given bulk of air. From the experiments of Humboldt it appears to vary from .005 to .01. Mr. Dalton's experiments give the quantity much smaller; he concludes that air contains only $\frac{1}{1000}$ th of its bulk of carbonic acid gas. Hence, and from the results of other experiments, it is inferred, that the bulk of carbonic acid in air, does not exceed much the $\frac{1}{1000}$ th part of the atmosphere.

From all which we conclude, that the average proportion of each of these three distinct elastic fluids, forming chiefly the whole body of the atmosphere, is,—

98.9 Air.
1.0 Vapour
0.1 Carbonic acid.
100.0

It is indeed true that other bodies, besides the three elastic fluids just mentioned, have been suspected in the atmosphere; as, for instance, hydrogen gas, and carburetted hydrogen; but as no satisfactory accounts concerning their quantities have yet been ascertained, or that would justify any particular notice of them in this place, we will therefore content ourselves by barely mentioning them, and refer our readers for the little information we have been able to collect respecting them, to their proper articles. The electric matter, and other substances raised from bodies on the earth's surface, by effluvia, exhalations, &c., are always distinguishable; and, being exposed to the continual action of the sun, give rise to innumerable operations, sublimations, separations, compositions, digestions, fermentations, putrefactions, &c. Thomson's Chem. vol. 4.

Electricity of the ATMOSPHERE. The subject of atmospheric electricity has engaged the attention of many Vol. I.

very eminent philosophers; since it is well known that, besides those large quantities of the electrical matter, with which the clouds are generally charged in a thunder storm, the atmosphere is never wholly destitute of the electric fluid. A person electrified negatively may satisfy himself of this by extending his arm in the open air, and presenting a long sharp needle with its point upwards; for the electric matter collected from the remoter air will appear luminous as it converges to the point of the needle. Mr. Canton's balls are likewise an excellent contrivance for the same purpose, and may be made use of, not only for determining the electricity of the atmosphere in general, but the positive or negative quality of it. According to this ingenious philosopher, desiccated atmospheric air, when heated, becomes negatively electric; and when cooled, the electricity is of the positive kind, even when the air is not permitted to expand or contract; and the expansion or contraction of atmospheric air occasions changes in its electrical state.

Becaria informs us, that the electricity of the atmosphere is always positive during the day, and in dry weather; but always negative when a bright or serene atmosphere succeeds dark and moist weather: that the quantity of it increases after the rising of the sun, and during his progress; and that its augmentation is the more considerable as the moisture of the air diminishes; but it decreases in the evening. In days equally dry, the degree of electricity at noon was proportional to the degree of heat; and in a serene atmosphere with little wind, a considerable quantity of the electrical matter commonly arose after sun-set during the precipitation of the dew. Thick fogs were observed, during their ascent into dry air, to carry with them a considerable quantity of the electric matter. And the electricity was always stronger when his rods were higher, and the strings which were extended and insulated in the open air were longer. See his Essay on Atmospheric Electricity annexed to the English translation of his Artificial Electricity.

Mr. Cavallo, from numerous experiments and observations, infers, that there is in the atmosphere at all times a quantity of electric matter:—that the electricity of the atmosphere and of fogs is always positive:—that in general the strongest electricity is observable in thick fogs, and also in frosty weather; and the weakest when it is cloudy and warm, and rain approaches;—that it does not seem to be less by night than by day; and that it is stronger in places more elevated, than in those which are lower. See his complete Treatise on Electricity, vol. 2. p. 42. edit. 4.

Among the celebrated men who have engaged in the cultivation of this science, few have enjoyed the advantages of observing the phenomena attending atmospherical electricity of M. Saussure, or indeed who have possessed a more extensive acquaintance with meteorology in general, for enabling him to illustrate these phenomena, by appropriate observations. He confirms the fact, noticed by others, and previously known, that aerial electricity varies according to the situation, being generally strongest in elevated and insulated places, and not observable under trees, in streets, houses, &c. But it is not so much the height as the situation of the places which determines the degree of electricity: for the projecting angle of a high hill, he says, will often exhibit a stronger electricity than the plain at the top of the hill, as there are fewer points of the former to deprive the air of its electricity. The intensity of the atmospherical electricity is also subject to a great variety

of changes, of which some depend on obvious circumstances, while others are altogether inexplicable; they are sometimes so rapid, says Saussure, as to preclude all possibility of noting them down. When rain falls, without a storm, these changes are not so sudden; but with respect to the intensity of the electric force, they are excessively irregular; while the quality of it is more constant. Rain or snow almost always gives positive electricity. In cloudy weather, without rains or storms, the electricity generally follows the same laws as in serene weather. Its intensity is most commonly diminished by strong winds, which blend the different strata of the atmosphere, cause them to subside towards the ground, and thus distribute the electricity uniformly between the earth and the air. The various modifications of electricity in the atmosphere, are observed with the greatest advantage in serene weather. M. Saussure found in winter, and in such weather, that the electricity was generally weakest in the evening, when the dew had fallen, and so continued till sun-rise; afterwards its intensity augmented by degrees, sometimes sooner and sometimes later; but usually before noon it attained a certain maximum, from which it again declined till the fall of the dew, when it would be sometimes stronger than it had been during the whole day; after which, it would again gradually decrease during the whole night; but it was never quite destroyed in weather perfectly serene. Hence it may be inferred, that atmospherical electricity, like the waters of the ocean, is subject to a flux and reflux; which produce an increase and diminution twice in 24 hours. The same author also remarks, after numerous experiments made on evaporation, that this which appeared to be the vehicle that conveys electric matter into the atmosphere, from silver and china always produced negative electricity; and from iron and copper—generally positive electricity: and hence it may be inferred, that electricity is positive with those bodies that are capable of decomposing water, or of being decomposed themselves by their contact with the water; and negative with all those that are not at all decomposed or altered.

As to the producing causes or sources of atmospherical electricity, we may observe in general, that they may be reduced to four, viz, friction, evaporation, heat and cold, and condensation and expansion: and with respect to the changes and modifications to which the atmospherical electricity is continually subject, they may be attributed to the operation of the various causes that produce them, and to the chemical processes that are constantly carried on by means of the various ingredients that compose the atmosphere. For further observations on this subject, consult the authors from whence these particulars were chiefly taken; also Mr. Read's very ingenious work, entitled a Summary View of the Spontaneous Electricity of the Earth and Atmosphere. See also the articles HAIL, RAIN, SNOW, LIGHTNING, and those of other meteors.

Figure of the ATMOSPHERE.—As the atmosphere envelops all parts of the surface of our globe, it is evident, if they both continued at rest, and were not endowed with a diurnal motion about their common axis, that the atmosphere would be exactly globular, according to the laws of gravity; for all the parts of the surface of a fluid in a state of rest, must be equally removed from its centre. But as the earth and the ambient parts of the atmosphere revolve uniformly together about their axis, the different parts of both have a centrifugal force, the tendency of which is more considerable, and that of the centripetal less, as the

parts are more remote from the axis; and hence the figure of the atmosphere must become an oblate spheroid; since the parts that correspond to the equator are farther removed from the axis, than the parts which correspond to the poles. Besides, the figure of the atmosphere must, on another account, represent a flattened spheroid, namely because the sun strikes more directly the air which encompasses the equator, and is comprehended between the two tropics, than that which pertains to the polar regions; whence it follows, that the mass of air, or part of the atmosphere, adjoining to the poles, being less heated, cannot expand so much, nor reach so high. Yet, notwithstanding, as the same force which contributes to elevate the air, diminishes its pressure on the surface of the earth, higher columns of it about the equatorial parts, all other circumstances being the same, may not be heavier than those about the poles.

In the Transactions of the Royal Irish Academy for 1788, Mr. Kirwan has an ingenious dissertation on the figure, height, weight, &c, of the atmosphere. He observes that, in the natural state of the atmosphere, that is, when the barometer would every where, at the level of the sea, stand at 30 inches, the weight of the atmosphere, at the surface of the sea, must be equal all over the globe; and in order to produce this equality, as the weight proceeds from its density and height, it must be lowest where the density is greatest, and highest where the density is least; that is, highest at the equator and lowest at the poles, with several intermediate gradations.

Though the equatorial air however be less dense to a certain height than the polar, yet at some greater heights it must evidently be more dense: for since an equatorial and polar column are equal in total weight or mass, the lower part of the equatorial column, being more expanded by heat &c than that of the polar, must have less mass, and therefore a proportionably greater part of its mass must be found in its superior section; so that the lower extremity of the superior section of the equatorial column is more compressed, and consequently denser, than the corresponding part of the polar column. The same thing is to be understood also of the extra-tropical columns with respect to each other, where differences of heat prevail.

Hence, in the highest regions of the atmosphere, the denser equatorial air, not being supported by the collateral extra-tropical columns, gradually flows over, and expands itself towards the north and south.

These superior tides consist chiefly of inflammable air, as it is much lighter than any other, and is generated in great plenty between the tropics; it furnishes the matter of the aurora borealis and australis, by whose combustion it is destroyed, otherwise its quantity would in time become too great, and the weight of the atmosphere annually increased; but its combustion is the primary source of the greatest perturbations of the atmosphere. See an ingenious work on the Atmosphere by H. Robertson, M. D. in 2 vols. 8vo, 1808.

Weight or Pressure of the ATMOSPHERE.—That the mass of the atmosphere has weight, and consequently presses upon bodies exposed to its action, is a fact which has been asserted by almost all philosophers, both ancient and modern. But it was only by means of the experiments made with pumps and the barometrical tube, by Galileo and Torricelli, that we have been convinced of its reality, and enabled to ascertain the precise measure and quantity of that pressure. Thus, it is found that the pres-

sure of the atmosphere sustains a column of quicksilver, in the tube of the barometer, of about 30 inches in height; it therefore follows, that the whole pressure of the atmosphere is equal to the weight of a column of quicksilver, of an equal base, and 30 inches height: and because a cubical inch of quicksilver is found to weigh nearly half a pound avoirdupois, therefore the whole 30 inches, or the weight of the atmosphere on every square inch of surface, is almost equal to 15 pounds. Again, it has been found that the pressure of the atmosphere balances, in the case of pumps &c, a column of water of about $34\frac{1}{2}$ feet high; and, the cubical foot of water weighing just 1000 ounces, or $62\frac{1}{2}$ pounds, $34\frac{1}{2}$ times $62\frac{1}{2}$, or 2158lb, will be the weight of the column of water, or of the atmosphere on a base of one square foot; and consequently the 144th part of this, or 15lb nearly, is the weight of the atmosphere on a square inch; the same as before. Hence Mr. Cotes computed that the pressure of this ambient fluid on the whole surface of the earth, is equivalent to that of a globe of lead of 60 miles in diameter. And hence also it appears, that the pressure upon the human body must be very considerable; for as every square inch of surface sustains a pressure of 15 pounds, every square foot will sustain 144 times as much, or 2160 pounds; then, if the whole surface of a man's body be supposed to contain 15 square feet, which is pretty near the truth, he must sustain 15 times 2160, or 32400 pounds, that is nearly $14\frac{1}{2}$ tons weight, for his ordinary load. By this enormous pressure we should undoubtedly be crushed in a moment, if all parts of our bodies were not filled either with air or some other elastic fluid, the spring of which is just sufficient to counterbalance the weight of the atmosphere. But whatever this fluid may be, it is certain that it is just able to counteract the weight of the atmosphere, and no more: for, if any considerable pressure be superadded to that of the air, as by going into deep water, or the like, it is always severely felt, at least when the change is made suddenly; and if, on the other hand, the pressure of the atmosphere be taken off from any part of the human body, as the hand for instance, when put over an open receiver, from which the air is afterwards extracted, the weight of the external atmosphere then prevails, and we imagine the hand strongly sucked down into the glass.

The difference in the weight of the air which our bodies sustain at one time more than another, is also very considerable; this difference in the same situation arises from changes in the state of the atmosphere, and it most frequently takes place in countries at some distance from the equator; and as the barometer varies at times from 28 to 31 inches, or about one tenth of the whole quantity, it follows that this difference amounts to about a ton and a half on the whole body of a man, which he therefore may sustain at one time more than at another. On the increase of this natural weight, the weather is commonly fine, and we feel ourselves in better spirits and more alert and active; but, on the contrary, when the weight of the air diminishes, the weather is generally moist and foggy, and people feel a listlessness and inactivity about them. And hence it is no wonder that persons suffer very much in their health from such changes in the atmosphere, especially when they take place very suddenly, for it is to this circumstance chiefly that a sensation of uneasiness and indisposition is to be attributed; thus, when the variations of the barometer and atmosphere are sudden and great, we feel the alteration and its effect on our bodies and spi-

rits very much; but when a change of this kind is gradual, we are scarcely sensible of it, owing, undoubtedly, to the power with which the body is naturally endowed, of accommodating itself to this alteration in the state of the air, as well as to the change of many other circumstances of life, the body requiring a certain interval of time to effect the alteration in its state, proper to that of the air &c. Thus, in going up to the tops of mountains, where the pressure of the atmosphere is diminished two or three times more than on the plain below, little or no inconvenience is felt from the rarity of the air, if it be not mixed with other noxious vapours &c; because that, in the ascent the body has had sufficient time to accommodate itself gradually to the slow variation in the state of the atmosphere: but, when a person ascends with a balloon very rapidly to a great height in the atmosphere, he feels a difficulty in breathing and an uneasiness of body; and the same is also true of an animal when inclosed in a receiver, and the air suddenly drawn or pumped out of it. So likewise, on the condensation of the air, we feel little or no change in ourselves, except when the alteration occurs suddenly, as in very rapid changes in the weather, and in descending to great depths in a diving-bell, &c. I have often heard the late unfortunate Mr. Spalding speak of his experience on this point: he always found it absolutely necessary to descend with the bell very slowly, and that only from one depth to another, resting a while at each depth before he began to descend farther: he first descended slowly for about 5 or 6 fathom, and then stopped a while; he felt an uneasiness in his head and ears, which increased more and more as he descended, till he was obliged to stop at the depth above mentioned, where the density of the air was nearly doubled; having remained there a while, he felt his ears give a sudden crack, and after that he was soon relieved from any uneasiness in that part, and it seemed as if the density of the air was not altered. He then descended 30 feet more, with the same precaution and similar sensations, being again relieved in the same manner, after remaining a while stationary at the next stage of his descent, where the density of the air was tripled. And thus he continued proceeding to a great depth, always with the same circumstances, repeated at every 5 or 6 fathoms, and adding the pressure of one more atmosphere at every period of the progress.

It is not easy to assign the true reason for the variations that happen in the gravity of the atmosphere in the same place. In places within the tropics, where these variations are not very considerable, the chief cause seems to be the heat of the sun, as the barometer constantly sinks about half an inch every day, and rises to its former station again in the night. But in the temperate zones the barometer ranges from 28 to near 31 inches, showing, by its various altitudes, the changes that are about to take place in the weather. If we could know, therefore, the causes by which the weather is influenced; we should also know those by which the gravity of the atmosphere is affected. These may perhaps be reduced to immediate ones, viz, an emission of latent heat from the vapour contained in the atmosphere, or of electric fluid from the same, or from the earth; as it is observed that they both produce the same effect with the solar heat in the tropical climates, viz, to rarefy the air, by mixing with it, or setting loose a lighter fluid, which did not before act in such large proportion in any particular place.

Temperature of the ATMOSPHERE.—To no part of natural

and experimental philosophy, has the attention of learned men been directed with greater assiduity, than that which respects the various states of the atmosphere in regard to temperature: many reasons have been adduced, as well as theories proposed, to account for these phenomena, and numerous experiments made to ascertain the precise degrees of variation, at different seasons, and in different situations, both at sea and land. Among the writers who have rendered themselves conspicuous in these investigations, are Dr. Hales, M. Bouguer, Mariotte, Halley, Dé Luc, Saussure, Mairan, Raymond, Playfair, Kirwan, and Darwin. They all agree, that the principal alterations in the state of the atmosphere are effected by means of the sun's heat, and that arising from the condensation of vapour: it was from the former fact that the ancient philosophers of Greece and Rome concluded (though too abruptly) that the torrid zone under a vertical sun, and the frigid zone where its rays fall very obliquely, were uninhabitable: time corrected this mistake, and presented new phenomena, which it has been found difficult to explain. The hottest days are frequently felt in the coldest climates; and the greatest cold, as well as perpetual snow, are found in countries bordering on, or even immediately under, the equator. Dr. Halley has indeed proved, that abstracting from the intervention of fogs, mists, and mountains of ice, the hottest weather might in summer take place even under the poles; the duration of the sun's light more than compensating for the obliquity of its direction, (see *HEAT*); but as many physical causes obstruct the activity of the solar rays in these and other regions, it was still necessary to recur to some other cause. At length M. de Mairan (*Mem. Acad. Paris, 1719 and 1767*) discovered, that the rigour or intensity of the cold in winter, is tempered by the heat imparted to the atmosphere by the earth itself; which heat, probably possessed from its origin, is preserved and renewed by the incessant influences of the sun, to which one half of its surface is constantly exposed: hence it must follow, that the temperature of the atmosphere depends on the capacity of the earth to receive and retain heat, and for communicating it to the surrounding medium. But as the earth is composed of land and water, it should be considered that the capacities of these constituent parts, for receiving both heat and cold, are very different. Land, particularly when dry, receives heat from the sun's rays very readily, but transmits it through its own substance to great depths very slowly; and on the other hand water, by reason of its transparency, receives heat very slowly, but diffuses what it receives more readily. The experiments of Dr. Hales, and those of other philosophers, to ascertain the degrees of heat of the earth at different depths, and at various times of the year, appear to confirm the idea that the surface of the earth is much heated during the summer, but that the heat descends very slowly, a great part of it being communicated to the air; and that during the winter, the earth gives out to the air the heat which it had received during the summer; also that wet summers must be succeeded by cold winters. Mariotte, also obtained nearly the same results: he found that the earth is gradually heated during the summer, and as gradually cooled during the winter months; and that at the distance of a few feet under the surface, it is constantly warmer than the external air; and the excess was found to remain till April, when the surface is again heated by the sun's rays, and slowly transmits its heat downwards. Hence it appears, that at the

distance of about 80 or 90 feet below the surface, provided there be a communication with the external air, or at a less depth if there be no such communication, the temperature of the earth admits of very slight variation, and generally approaches to the mean annual heat. From which it has been inferred, that the temperature of spring is nearly the same as the annual temperature, and varies very little. These facts tend to prove very satisfactorily, that the heat of the earth does not increase as we descend below its surface, but at the greatest depths it is nearly the same as the mean annual temperature of the latitude. We have observed, that land is capable of receiving heat and cold much more readily than water. To which purpose Dr. Raymond found, in the neighbourhood of Marseilles, land frequently heated to 160° ; but he never observed that the sea was hotter than 77° ; and in winter he frequently observed the earth cooled down to 14° or 15° , but the sea never lower than 44° or 45° : *Mem. de la Societ. de Med. de Paris, an. 1778, p. 70.* From these facts therefore, it must follow, that the atmosphere which lies over the sea should maintain a more uniform temperature, than that over the land; and this is found to be the fact; nor is it difficult to give a satisfactory explication of it. During summer, the temperature of the sea on its surface is constantly diminished by the process of evaporation; and in the winter, when the superficial water is cooled, it descends by its augmented gravity to the bottom, and its place is occupied by water of a higher temperature. Thus alternate changes of heavier and lighter air proceed, and the winter elapses before the atmosphere has diminished the temperature of the water below a certain degree. Between the mean annual temperature of the atmosphere over the ocean, and that of countries situated at a considerable distance from it, there is a very perceptible difference. As the sea is never heated to the same degree as the land, the mean temperature of summer over the sea may be considered as lower than that over the land. In winter, when the force of the sun's rays is weakened, the sea imparts its heat to the atmosphere much more readily than the earth; therefore the mean temperature on sea, at this season, is higher than on land; and in cold countries, this difference in the evolution of heat is so very considerable, that it more than counterbalances the difference which takes place in summer; insomuch that, in high latitudes, the mean annual temperature at sea ought to exceed that on land.

In latitudes distant from the equator, islands are warmer than continents, because they participate more of the temperature of the sea. Countries that lie southward of any sea, are warmer than those that have the sea to the south of them, at least in our hemisphere, because the winds that should cool them in winter are tempered by passing to them from that sea; and those that are northward of the sea, are cooled in summer by the breezes that issue from it; but a northern or southern bearing of the sea renders a country warmer than if it lay either to the east or west. Tracts of land which are covered with trees and luxuriant vegetables, are much colder than those which have less surface of vegetable matter; for though living vegetables alter their temperature slowly and with difficulty, yet the evaporation from their numerous surfaces is much greater than from the same space of land uncovered with vegetables; and besides, when they are tall and close, as forests, they exclude the sun's rays, and shelter the winter snows from the wind and sun. From some experiments of Mr.

Williams (Philad. Trans. vol. 2, p. 150), it appears that forests discharge one third more vapour into the atmosphere, than the same space of ground would do if actually covered with water. From this reasoning it seems that woody countries are much colder than those that are open and cultivated. With regard to the heat afforded from the condensation of vapour, we need not expatiate very considerably, since it is well known that vapour contains a great quantity of such matter. This heat produces no other effect but that of making it assume an aerial expanded form, until the vapour is condensed into a liquid; and during this condensation, a quantity of sensible heat is let loose, which warms the surrounding atmosphere. This condensation is frequently occasioned by the attraction of an electrical cloud; and hence proceeds the sultriness which we often experience before rain.

The following is a view of the annual temperature of different places according to the order of their latitudes.

	North Lat.	Longitude	Mean Annual Heat.

As to the effect of elevation on the temperature of the atmosphere, we may observe, that as heat is propagated through the atmosphere chiefly by communication and contact with the earth, lofty mountains of limited surface cannot warm it to any considerable degree, as they receive the sun's rays more obliquely, and communicating less with the common mass of the earth, are less heated than plains. Hence it happens that the steepest mountains are always the coldest. Before M. Bouguer demonstrated and laid open the true causes of the diminution of heat on the tops of mountains, many hypotheses were assumed to account for this phenomenon; but this celebrated philosopher has shown, that there is no necessity for recurring to any dubious suppositions for an explication of the fact, as will evidently appear from his account of what was experienced on the mountains of Peru. He says, "It was proper, in order to explain this subject, to consider the short duration of the sun's rays, which cannot strike the different sides of mountains but for a few hours, and even this not always. A horizontal plain, when the sun is clear, is exposed at mid-day to the perpendicular and undiminished action of these rays, while they fall but obliquely on a plain not much inclined, or on the sides of a high pile of steep rocks. But let us conceive for a moment an insulated point, half the height of the atmosphere, at a distance from all mountains, as well as from the clouds which float in the air. The more a medium is transparent, the less heat it ought to receive by the immediate action of the sun. The free passage which a very transparent body allows to the rays of light, shows that its small particles are hardly touched by them. Indeed, what impression could they make on it when they pass through almost without obstruction? Light, when it consists of parallel rays, does not, by passing through a foot of free atmospheric air near the earth, lose an hundred-thousandth part of its force. From this we may judge how few rays are weakened, or can act upon this fluid, in their passage through a stratum of the diameter, not of an inch or line, but of a particle; yet the subtlety or transparency are still greater at greater heights, as was obvious in the Cordilleras when we looked at distant objects. Lastly, the grosser air is heated below by the contact or neighbourhood of bodies of greater density than itself, which it surrounds and on which it rests; and the heat may be communicated by small degrees to a certain distance. The inferior part of the atmosphere by this means contracts daily a very considerable degree of heat, and may receive it in proportion to its density or bulk; but it is evident that the same thing cannot happen at the distance of a league and a half or two leagues above the surface of the earth, though the light may be there something more active. The air and wind, therefore, at this height, must be extremely cold, and colder in proportion to its elevation."

Sauurre adopts this theory, and adds the following fact, to prove that the force of the sun's rays, considered abstractedly and independently of any extrinsic source of cold, is no less powerful on mountains than on plains, viz, that the power of burning lenses and mirrors is the same at all heights. For ascertaining this fact, he procured a burning glass so weak in its effect, that at Geneva it would just set fire to tinder. This glass was carried to the summit of Mount Saleve, 3000 feet high, and it there produced the same effect, and with greater ease. Hence he concluded that the principal source of cold on the tops of mountains is their being perpetually surrounded by an

atmosphere which cannot be much heated by the rays of the sun, on account of its transparency, or by their reflection from the earth, by reason of its distance; but he wished also to know whether the direct solar rays had the same power on the top of a high mountain as on the plain below, while the body on which they acted was placed in such a manner as to be unaffected by the surrounding air. With this view he instituted a set of experiments, from which he deduced the following conclusions, viz., that a difference of 777 toises in height, diminishes the heat which the rays of the sun are able to communicate to a body exposed to the external air, 14° of the thermometer; that it diminishes the heat of a body partially exposed only 6°; and that it augments by 10° the heat of a third body completely defended from the air. Hence it appears, that the atmosphere counteracts the operations of the solar rays in producing heat, by a power which is exerted at all distances, from the surface to the higher regions.

Dr. Darwin, from his experiments and observations, infers, that there is good reason for concluding that in all circumstances where air is mechanically expanded, it becomes capable of attracting the fluid matter of heat from other bodies in contact with it. Now, as the vast region of air which surrounds our globe is perpetually moving along its surface, rising up the sides of mountains, and descending into the valleys; as it passes along, it must be perpetually varying the degree of heat, according to the elevation of the country it traverses: for, in rising to the summits of mountains, it becomes expanded, having so much of the pressure of the superincumbent atmosphere taken away; and when thus expanded, it attracts or absorbs heat from the mountains in contiguity with it; and, when it descends into the valleys, and is compressed into less compass, it again gives out the heat it has acquired to the bodies it comes in contact with. The same thing must happen to the superior regions of the atmosphere, which are regions of perpetual frost, as has lately been evinced by the aerial navigators. When large districts of air, from the lower parts of the atmosphere, are raised two or three miles high, they become so much expanded by the great diminution of the pressure over them, and thence become so cold, that hail or snow is produced by the precipitation of the vapour: and as there is, in these high regions of the atmosphere, nothing else for the expanded air to acquire heat from after it has parted with its vapour, the same degree of cold continues, till the air, on descending to the earth, acquires its former state of condensation and of warmth. The Andes, almost under the line, rests its base on burning sands: about its middle height is a most pleasant and temperate climate covering an extensive plain, on which is built the city of Quito; while its forehead is encircled with eternal snow, perhaps coeval with the mountain. Yet, according to the accounts of Don Ulloa, these three discordant climates seldom encroach much on each other's territories. The hot winds below, if they ascend, become cooled by their expansion; and hence they cannot affect the snow upon the summit; and the cold winds that sweep the summit become condensed as they descend, and of a moderate temperature before they reach the fertile plains of Quito.

Many other experiments to this purpose were also made by M. Pictet of Geneva, Dr. Wilson of Glasgow, and Mr. James Six; but as our limits will not permit us to give observations of this kind in detail, we beg to refer our readers

to the works containing them; viz., the 76th vol. of the Phil. Trans. for Mr. James Six's, and the same Trans. for 1780 and 1781, for Dr. Wilson's: also see Rees's new edit. of his Cyclopaedia, art. Atmosphere.

Height and Density of the Atmosphere. Various attempts have been made to ascertain the height to which the atmosphere extends above the earth. These commenced soon after it was discovered, by means of the Torricellian tube, that air is endued with weight and pressure. And had not the air an elastic power, but were every where of the same density, from the surface of the earth to the extreme limit of the atmosphere, like water, which is equally dense at all depths, it would be a very easy matter to determine its height from its density and the column of mercury which it would counterbalance in the barometrical tube: for, it having been observed that the weight of the atmosphere is equivalent to a column of about 30 inches or 2½ feet of quicksilver, and the density of the former to that of the latter, nearly as 1 to 11040; therefore the height of the uniform atmosphere would be 11040 times 2½ feet, that is 27600 feet, or little more than 5 miles and a quarter. But the air, by its elastic quality, expands and contracts; and it being found by repeated experiments in most nations of Europe, that the spaces it occupies, when compressed by different weights, are reciprocally proportional to those weights; or, that the more air is pressed, so much the less space it takes up; it follows that the air in the upper regions of the atmosphere must become continually more and more rare, as the height of it increases, and thus, according to that law, must necessarily be extended to an indefinite height. Now, if we suppose the height of the whole to be divided into innumerable equal parts, the quantity of each part will be as its density; and the weight of the whole incumbent atmosphere being also as its density; it follows, that the weight of the incumbent air is every where as the quantity contained in the subjacent part; which causes a difference between the weights of each two contiguous strata of air. But, by a theorem in the doctrine of proportion, when a magnitude is continually diminished by the like part of itself, and the remainders the same, they will express a series of continued quantities decreasing in geometrical progression: therefore if, according to the supposition, the altitude of the air, by the addition of new parts into which it is divided, do continually increase in arithmetical progression, its density will be diminished, or, which is the same thing, its gravity will be decreased, in continued geometrical progression. And hence, again, it appears that, according to the hypothesis of the density being always proportional to the compressing force, the height of the atmosphere must necessarily be extended indefinitely. And, farther, as an arithmetical series adapted to a geometrical one, is analogous to the logarithms of the said geometrical one; it follows therefore that the altitudes are proportional to the logarithms of the densities or weights of air; and that any height taken from the earth's surface, which is the difference of two altitudes to the top of the atmosphere, is proportional to the difference of the logarithms of the two densities there, or to the logarithm of the ratio of those densities, or their corresponding compressing forces, as measured by the two heights of the barometer there. This law was first observed and demonstrated by Dr. Halley, from the nature of the hyperbola; and afterwards by Dr. James Gregory, by means of the logarithmic curve. See Philos. Trans. N° 181, or my Abridg. vol. 3, p. 300, and Greg. Astron. lib. v, prop. 3.

It is now easy, from the foregoing property, and two or three experiments, or barometrical observations, made at known altitudes, to deduce a general rule to determine the absolute height answering to any density, or the density answering to any given altitude above the earth. And accordingly, calculations have been made upon this plan by many philosophers, particularly by the French; but it having been found that the barometrical observations did not correspond with the altitudes as measured geometrically, it was suspected that the upper parts of the atmospherical regions were not subject to the same laws with the lower ones, in regard to the density and elasticity. And indeed, when it is considered that the atmosphere is a heterogeneous mass of particles of all sorts of matter, some elastic, and others not, it is not improbable but this may be the case, at least in the regions very high in the atmosphere, which it is likely may more copiously abound with the electrical fluid. Be this however as it may, it has lately been discovered that the law above given, holds very well for all such altitudes as are within our reach, or as far as to the tops of the highest mountains on the earth, when a correction is made for the difference of the heat or temperature of the air only; as was fully evinced by M. de Lue, in a long series of observations, in which he determined the altitudes of hills, both by the barometer and by geometrical measurement, from which he deduced a practical rule for determining the allowance to be made for the difference of temperature. See his Treatise on the Modifications of the Atmosphere. Similar rules have also been deduced from accurate experiments, by Sir George Shuckburgh and General Roy, both concurring to shew, that such a rule for the altitudes and densities holds true for all heights that are accessible to us, when the elasticity of the air is corrected on account of its density: and the result of their experiments showed that the difference of the logarithms of the heights of the mercury in the barometer, at two stations, when multiplied by 10000, is equal to the altitude in English fathoms, of one place above the other; that is, when the temperature of the air is about 31 or 32 degrees of Fahrenheit's thermometer; and a certain quantity more or less, according as the actual temperature is different from that degree.

But it may here be shown that the same rule can be deduced independent of such a train of experiments as those above, and that from a single observation of the density of the air at the surface of the earth alone. Thus, let ρ denote the density of the air at one place, and d the density at the other; both measured by the column of mercury in the barometrical tube: then the difference of altitude between the two places, will be proportional to the log. of $\rho - d$ — the log. of d , or to the log. of $\frac{\rho}{d}$. But as this formula expresses only the relation between different altitudes, and not the absolute quantity of them, assume some indeterminate but constant quantity h , which multiplied into the expression $\log. \frac{\rho}{d}$, may be equal to the real difference of

altitude a , that is $a = h \times \log. \frac{\rho}{d}$. Then, to determine the value of the general quantity h , let us take a case in which we know the altitude a which corresponds to a known density ρ ; as for instance, $a = 1$ foot, or 1 inch, or some such small altitude: then because the density ρ may be measured by the pressure of the whole atmosphere, or the uniform column of 27600 feet, when the temperature is

55°; therefore 27600 feet will denote the density ρ at the lower place, and 27599 the less density d at 1 foot above it; consequently $1 = h \times \log. \frac{27600}{27599}$, which is nearly $= h \times \frac{43429448}{27600}$ or $\frac{1}{63551}$ by the nature of logarithms; and hence we find $h = 63551$ feet; which gives us this formula, for any altitude a in general, viz, $a = 63551 \times \log. \frac{\rho}{d}$, or $a = 63551 \times \log. \frac{m}{m'}$ feet, or $10592 \times \log. \frac{m}{m'}$ fathoms; where m denotes the column of mercury in the tube at the lower place, and m' that at the upper. This formula is adapted to the mean temperature of the air 55°; but it has been found, by the experiments of Sir Geo. Shuckburgh and General Roy, that for every degree of the thermometer, different from 55°, the altitude a will vary by its 435th part; hence, if we would change the factor h from 10592 to 10000, because the difference 592 is nearly the 18th part of the whole factor 10592, or sufficiently so for all practical purposes, and 18 the 24th part of 435; therefore the change of temperature, answering to the change of the factor h , is 24°, which reduces the 55° to 31°. So that, $a = 10000 \times \log. \frac{m}{m'}$ fathoms, is the easiest expression for the altitude, and answers to the temperature of 31°, or very nearly the freezing point: and for every degree above that, the result must be increased by so many times its 435th part, and diminished when below it.

From this theorem it follows, that, at the height of 3½ miles, the density of the atmosphere is nearly 2 times rarer than it is at the surface of the earth; at the height of 7 miles, 4 times rarer; and so on, according to the following table:

Height in miles.	Number of times rarer.
3½	2
7	4
14	16
21	64
28	256
35	1024
42	4096
49	16384
56	65536
63	262144
70	1048576

And, by pursuing the calculations in this table, it might be easily shown, that a cubic inch of the air we breathe would be so much rarefied at the height of 500 miles, that it would fill a sphere equal in diameter to the orbit of Saturn.

Hence we may perceive how very soon the air becomes so extremely rare and light, as to be utterly imperceptible to all experience; and that hence, if all the planets have such atmospheres as our earth, they will, at the distances of the planets from one another, be so extremely attenuated, as to give no sensible resistance to the planets in their motion round the sun, for many, perhaps hundreds or thousands of ages to come. Even at the height of 50 miles, it is so rare as to have no sensible effect on the rays of light: for it was found by Kepler, and Lahire after him, who computed the height of the sensible atmosphere from the duration of twilight, and from the magnitude of the terrestrial shadow in lunar eclipses, that the effect of the atmosphere to reflect and intercept the light of the sun, is

only sensible to the altitude of between 40 and 50 miles; and at that altitude we may collect, from what has been already said, that the air is above 10000 times rarer than at the surface of the earth. It is well known that the twilight begins and ends when the centre of the sun is about 18 degrees below the horizon, or only $17^{\circ} 27'$, by subtracting 3° for refraction, which raises the sun so much higher than he would be. And a ray coming from the sun in that position, and entering the earth's atmosphere, is refracted and bent into a curve line in passing through it to the eye. M. Lahire took great pains to demonstrate, that, supposing the density of the atmosphere proportional to its weight, this curve is a cycloid; he also says, that if the ray be a tangent to the atmosphere, at the point of impact, the diameter of its generating circle will be the height of the atmosphere; and that this diameter increases, till at last, when the rays are perpendicular, it becomes infinite, or the circle degenerates into a right line. This reasoning supposes that the refracting surface of the atmosphere is a plane; but since it is in reality a curve, he observes that these cycloids become in fact epicycloids. Herman however detected the error of M. Lahire, and showed that this curve is infinitely extended, and has an asymptote. And it is observed by Dr. Brook Taylor, in his Method. Increment. p. 168, &c., that this curve is one of the most intricate and perplexed that can well be proposed. The same ingenious author also computes, that the refractive power of the air is to the force of gravity at the surface of the earth, as 320 millions to 1.

The extreme rarity of the atmosphere at considerable distances from the earth's surface, such as those of 40 or 50 miles, bounding the production of twilight, has much perplexed philosophers in accounting for meteors which, whatever be their origin, whether electrical or otherwise, are observed at a much greater elevation than that to which the refractive power of the atmosphere extends. A very remarkable one of this kind was observed by Dr. Halley in the month of March 1719, the altitude of which he computed at between 69 and $73\frac{1}{2}$ English miles; its diameter 2800 yards, or more than a mile and a half; and its velocity about 350 miles in a minute. Others, apparently of the same kind, but whose altitude and velocity were still greater, have been observed; particularly that very remarkable one, of August 18th 1783, whose distance from the earth could not be less than 90 miles, and its diameter at least as large as the former, while its velocity was certainly not less than 1000 miles in a minute. Now, from analogy of reasoning, it seems very probable, that the meteors which appear at such great heights in the air, are not essentially different from those which are seen on or near the surface of the earth. The difficulty with regard to the former is, that at the great heights above-mentioned, the atmosphere ought not, according to computation, to have any density sufficient to support flame, or to propagate sound; and yet such meteors are commonly succeeded by one explosion or more, and it is said are even sometimes accompanied with a hissing noise as they pass over our heads. The meteor of 1719 was not only very bright, seeming for a short time to turn night into day, but was attended with an explosion that was heard over the whole island of Britain, causing a violent concussion in the atmosphere, and seeming to shake the earth itself: and yet, in the regions in which this meteor moved, the air ought to have been 300 thousand times rarer than the air we breathe, or 1000 times rarer than the vacuum

commonly made by a good air-pump. Dr. Halley offers a conjecture, indeed, that the vast magnitude of such bodies might compensate for the thinness of the medium in which they moved. But appearances of this kind are, by others, attributed to electricity; though the circumstances of them cannot well be reconciled to that cause; for the meteors move with various degrees of velocity; and though the electrical fire easily pervades the vacuum of an air-pump, yet it does not in that case appear in bright well-defined sparks, as in the open air, but rather in long streams resembling the aurora borealis; and from some late experiments it has been concluded that the electric fluid cannot even penetrate, or be apparent in a perfect vacuum.

Of the Refractive and Reflective Power of the Atmosphere. It has been observed above, that the atmosphere has a refractive power, by which the rays of light are bent from the right-lined direction, as in the case of the twilight; and many other experiments manifest the same virtue, which is the cause of various phenomena. Alhazen, the Arabian, who lived about the year 1100, seems to have been more inquisitive into the nature of refraction than former writers. But neither Alhazen, nor his follower Vitellio were acquainted with its just quantity, nor was it known to any tolerable degree of exactness, before Tycho Brahé, with his accustomed diligence, settled this point. This celebrated philosopher however did not discover, nor indeed did Kepler, in what manner the rays of light were refracted by the atmosphere. Tycho thought the refraction was chiefly caused by dense vapours, very near the earth's surface: while Kepler placed the cause wholly at the top of the atmosphere, which he thought was uniformly dense; and thence he determined its altitude to be little more than that of the highest mountains. But the true constitution of the density of the atmosphere, deduced afterwards from the Torricellian experiment, afforded a juster idea of these refractions, especially after it appeared, by a repetition of Mr. Lowthorp's experiment, that the refractive power of the air is proportional to its density. By this variation in the density and refractive power of the air, a ray of light, in passing through the atmosphere, is continually refracted at every point, and thereby made to describe a curve, and not a straight line, as it would have done were there no atmosphere, or were its density uniform.

The atmosphere has also a reflective power; and this power is the means by which objects are enlightened so uniformly on all sides. The want of this power would occasion a strange alteration in the appearance of things; the shadows of which would be so very dark, and their sides enlightened by the sun so very bright, that probably we could see no more of them than their bright haloes; so that for a view of the other halves, we must turn them half round; or if immoveable, must wait till the sun could come round upon them. Such apellucid unreflective atmosphere would indeed have been very commodious for astronomical observations on the course of the sun and planets among the fixed stars, visible by day as well as by night; but then such a sudden transition from darkness to light, and from light to darkness, immediately on the rising and setting of the sun, without any twilight, and even on turning to or from the sun at noon day, would have been very inconvenient and offensive to our eyes. However, though the atmosphere be greatly assistant in the illumination of objects, yet it must also be observed that it stops a great deal of light. By M. Bouguer's ex-

periments, it seems that the light of the moon is often 2000 times weaker in the horizon, than at the altitude of 66 degrees; and that the proportion of her light at the altitudes of 66 and 19 degrees, is about 3 to 2; and the lights of the sun must bear the same proportion to each other at those heights; which Bouguer made choice of, as being the meridian heights of the sun, at the summer and winter solstices, in the latitude of Croisic in France. Smith's Optics, Rem. 95.—For the atmosphere of the sun, moon, and planets, see the respective articles.

ATMOSPHERE of *Solid or Consistent Bodies*, is a kind of sphere formed by the effluvia, or minute corpuscles, emitted from them. Mr. Boyle endeavours to show, that all bodies, even the hardest and most coherent, as gems, &c, have their atmospheres.

ATMOSPHERE in Electricity, denotes that medium which is conceived to be diffused over the surface, as is generally supposed, of electrified bodies, and to some distance around them, and consisting of effluvia issuing from them; by which, other bodies immersed in it become endowed with an electricity contrary to that of the body to which the atmosphere belongs. This was first noticed at a very early period in the history of this science by Otto Guericke, and afterwards by the academicians *del Cimento*, who contrived to render the electric atmosphere visible, by means of smoke attracted by and uniting itself with a piece of amber, and gently rising from it, but vanishing as the amber cooled. Dr. Franklin exhibited this electric atmosphere with greater advantage, by dropping rosin on hot iron plates held under electrified bodies, from which the smoke arose and encompassed the bodies, giving them a very beautiful appearance. But the theory of electric atmospheres was not well explained and understood for a considerable time; and the investigation led to many curious experiments and observations. The experiments of Mr. Canton and Dr. Franklin prepared the way for the conclusion that was afterwards drawn from them by Mess. Wilcke and Epinus; though they retained the common opinion of electric atmospheres, and endeavoured to explain the phenomena by that means. The conclusion was, that the electric fluid, when there is a redundancy of it in any body, repels the electric fluid in any other body, when they are brought within the sphere of each other's influence, and drives it into the remote parts of the body, or quite out of it, if there be any outlet for that purpose.

By atmosphere, Epinus says, no more is to be understood than the sphere of action belonging to any body, or the neighbouring air electrified by it. Sig. Beccaria unites in the same opinion, that electrified bodies have no other atmosphere than the electricity communicated to the neighbouring air, and which goes with the air, and not with the electrified bodies. Mr. Canton also, having relinquished the opinion that electrical atmospheres were composed of effluvia from excited or electrified bodies, maintained that they only result from an alteration in the state of the electric fluid contained in it, or belonging to the air surrounding these bodies to a certain distance; for instance, that excited glass repels the electric fluid from it, and consequently beyond that distance makes it more dense; whereas excited wax attracts the electric fluid existing in the air nearer to it, making it rarer than it was before. In the course of experiments that were performed on this occasion, Mess. Wilcke and Epinus succeeded in charging a plate of air, by suspending large boards of wood covered with tin, with the flat sides parallel to one another, and at

some inches asunder: for they found, on electrifying one of the boards positively, that the other was always negative; and a shock was produced by forming a communication between the upper and lower plates. Beccaria has largely considered the subject of electric atmospheres, in his Artificial Electricity, p. 179 &c, Eng. edit. See also Dr. Priestley's Hist. of Electricity, vol. ii. scct. 5; and Cavallotti's Electricity, p. 241.

ATMOSPHERE, Magnetic, &c, is understood of the sphere within which the virtue of the magnet, &c, acts.

ATMOSPHERIC STONES. See AEROLITHS.

ATMOSPHERIC TIDES, certain periodical changes of the atmosphere, similar, in some respects, to those of the ocean, and produced, in a great measure, by the same causes.

There are two kinds of motion in the atmosphere which come under this denomination; the first is occasioned by the joint influence of the sun and moon on the body of air with which we are surrounded, in the same manner as they act upon the mass of water, and cause the flux and reflux of the ocean; the second is produced by the heat of the sun alone, which exerting upon the air its well known power of rarefaction and expansion, gives rise to those perpetual changes in the atmosphere, which follow him in his course, though such changes are not altogether observable or appreciable by us. The former of these are termed by the Abbé Mann attraction tides, and the latter heat tides. The tides of attraction, like those of the ocean, and from the like grounds, have at the same time, at two opposite ends of the globe, projecting parts, and these lie almost in that line which might be drawn from the centre of the earth to that of the moon. The heat tides, on the other hand, can take place only on one point of the globe, that is, in the point to which the sun is vertical. Their projecting parts will be directed towards that luminary, and nearly follow its movements.

Bacon, and the most eminent philosophers who have since written on the wind, unanimously observe, that the periods of the year most exposed to it are the two equinoxes; that storms are most frequent at the times of new and full moon, and particularly those which happen near the equinoxes; that at periods otherwise calm, a small breeze always takes place at high water; and that a small movement in the atmosphere is each time perceived a little after noon and midnight.

For the investigation of this subject, the abbé lays down the following principles. 1. The elasticity of fluids is in the inverse ratio of their density. 2. The force or elasticity of the air expands and contracts itself in the direct ratio of the weight with which it is loaded, and diffuses itself in the inverse ratio of the force with which it is compressed. 3. The air is rarefied, or diffuses itself, in the direct ratio of the quantity of heat which acts upon it. 4. The air, as well as all fluids in general, has a tendency to put itself in equilibrium, and does not rest till it has obtained it.

Our limits preclude the possibility of following the abbé in the application of these principles to the various phenomena of the subject in question; we therefore recommend to the attention of our readers the whole of his observations on the flux and reflux of the atmosphere, inserted from the Brussels Trans. in Tilloch's Phil. Mag. vol. 5. In the 7th vol. of that work is a paper On a periodical Variation of the Barometer, &c, by Luke Howard, esq. to which we also refer; and conclude by noticing the observations made by Humboldt near the equator: "I have

read," says he, "in the Transactions of the Bengal Society, that the barometer rises and falls there regularly every 24 hours. Here, in South America, its motion is more astonishing: there are four atmospheric tides every 24 hours, which depend only on the attraction of the sun; the mercury falls from 9 o'clock in the morning till 4 in the afternoon; it rises from 4 till 11 o'clock; it falls from 11 till half past 4 in the morning; and reascends from that time till 9 o'clock; neither winds, storms, nor earthquakes have any influence on this motion." See farther Laplace, *Exposition du Système du Monde*, liv. 4, ch. 32.

ATOM, a particle of matter indivisible on account of its solidity, hardness, and impenetrability; which preclude all division, and leave no vacancy for the admission of any foreign force to separate it into parts. As atoms are the first matter, it is necessary they should be indissoluble, that they may be incorruptible. Newton adds, It is also required that they be immutable, that the world may continue in the same state, and bodies be of the same nature now as formerly.

ATOMICAL PHILOSOPHY, or the doctrine of atoms, a system which accounted for the origin and formation of things, from the hypothesis that atoms are endued with weight and motion. This philosophy was first taught by Moschus, some time before the Trojan war; but it was most cultivated by Epicurus; whence it is called the Epicurean philosophy.

ATTRACTION, or ATTRACTIVE POWER, a general term used to denote the cause, power, or principle, by which all bodies mutually tend towards each other, and cohere, till separated by some other power. The laws, phenomena, &c. of attraction, form the chief subject of Newton's philosophy, being the principal agent of nature, in almost all her wonderful operations.

The principle of attraction, in the Newtonian sense of it, appears to have been first surmised by Copernicus. "As for gravity," says he, "I consider it as nothing more than a certain natural appetence (*appetentia*) which the Creator has impressed upon all the parts of matter, in order to their uniting or coalescing into a globular form, for their better preservation; and it is probable that the same power is also inherent in the sun and moon, and planets, that those bodies may constantly retain that round form in which we see them." *De Revol. O. b. Coelest.* lib. i, cap. 9. Kepler calls gravity a corporeal and mutual affection between similar bodies, in order to their union. *Ast. Nov. in Introd.* And he pronounced more positively, that no bodies whatever were absolutely light, but only relatively so; and consequently that all matter was subjected to the power and law of gravitation. *Ibid.*

The first in this country who adopted the notion of attraction was Dr. Gilbert, in his book *De Magnete*; and the next was the celebrated Lord Bacon, in his *Nov. Organ.* lib. ii, aphor. 36, 45, 48. *Sylv. cent. 1, exp. 33;* also in his treatise *De Motu*, particularly under the articles of the 9th and the 13th kinds of Motion. In France it was received by Fermat and Roberval; and in Italy by Galileo and Borelli.

But before Newton none appear to have had clearer ideas of the doctrine of universal gravitation, or to have approached so near the application of it to the laws of nature, as Dr. Hooke. This celebrated man, in his work entitled "An Attempt to prove the Motion of the Earth," seems to have embraced it in nearly the whole of its generality. The hypothesis on which the system of the world

is there explained, is grounded on the three following principles: 1. That all the celestial bodies have not only an attraction or gravitation towards their proper centres, but that they mutually attract each other within their sphere of activity. 2. That all bodies which have a simple and direct motion, continue to move in a direct line, if some force which operates without ceasing does not constrain them to describe a circle, an ellipse, or some other more complicated curve. 3. That attraction is so much the more powerful, as the attracting bodies are nearer to each other. Newton makes use of the word attraction, in common with the school philosophers, but at the same time very studiously distinguishes between the ideas. The ancient attraction was conceived to be a kind of quality inherent in certain bodies themselves, and arising from their particular or specific forms. But the Newtonian attraction is a more indefinite principle; denoting not any particular kind or mode of action; nor the physical cause of such action; but only a general tendency, a conatus accedendi, to whatever cause, physical or metaphysical, such effect be owing; whether to a power inherent in the bodies themselves, or to the impulse of an external agent. Accordingly, that author remarks, in his *Philos. Nat. Prin. Math.* "that he uses the words attraction, impulse, and propension to the centre, indifferently; and cautions the reader not to imagine that by attraction he expresses the modus of the action, or its efficient cause, as if there were any proper powers in the centres, which in reality are only mathematical points; or as if centres could attract." Lib. 1, p. 5. So, he "considers centripetal powers as attractions; though, physically speaking, it were perhaps more just to call them impulses." *Ib. p. 147.* He adds, "that what he calls attraction may possibly be effected by impulse, though not a common or corporeal impulse, or after some other manner unknown to us." *Optics, p. 322.*

Attraction, if considered as a quality arising from the specific forms of bodies, ought, together with sympathy, antipathy, and the whole tribe of occult qualities, to be exploded. But when these are set aside, there will remain innumerable phenomena of nature, and particularly the gravity or weight of bodies, or their tendency to a centre, that argue a principle of action seemingly distinct from impulse; where, at least, there is no sensible impulse concerned. Nay, what is more, this action, in some respects, differs from all impulse we know of; impulse being always found to act in proportion to the surfaces of bodies; whereas gravity acts according to their solid content, and consequently it must arise from some cause that penetrates or pervades the whole substance of them. This unknown principle, (we mean in respect of its cause, for its phenomena and effects are most obvious, with all its species and modifications,) is called attraction; being a general name, under which may be ranged all mutual tendencies, where no physical impulse appears, and which consequently cannot be accounted for on any known laws of nature.

And hence arise divers particular kinds of attraction; as Gravity, Magnetism, Electricity, &c., which are so many different principles, acting by different laws; and only agreeing in this, that we do not perceive any physical causes of them: but that, as to our senses, they may really arise from some power or efficacy in such bodies, by which they are enabled to act even upon distant bodies; though our reason absolutely disallows of any such action.

Attraction may be divided, with respect to the law it observes, into two kinds.

1. That which extends to a sensible distance. As the attraction of gravity, which is found in all bodies; and the attractions of magnetism and electricity, found only in particular bodies. The several laws and phenomena of each, see under their respective articles."

The attraction of gravity, called also among mathematicians the centripetal force, is one of the greatest and most universal principles in nature. We see and feel it operate on bodies near the earth, and find by observation that the same power (i. e. a power which acts in the same manner, and by the same rules, viz, always proportionally to the quantities of matter, and inversely as the squares of the distances) does also obtain in the moon, and the other planets, both primary and secondary, as well as in the comets; and even that this is the very power by which they are all retained in their orbits, &c. And hence, as gravity is found in all the bodies which come under our observation, it is easily inferred, by one of the established rules of philosophising, that it obtains in all others. And since it is found to be proportional to the quantity of matter in any body, it must exist in every particle of it: and hence it is proved that every particle in nature attracts every other particle.

From this attraction arises all the motion, and consequently all the mutation, in the universe. By this heavy bodies descend, and light ones are made to ascend: by this also projectiles are directed, vapours and exhalations rise, and rain, &c, fall: also from the same cause rivers glide, the ocean swells, the air presses, &c. In short, the motions and forces arising from this principle, constitute the subject of that extensive branch of mathematics, called mechanics or statics, with the parts or appendages of it, as hydrostatics, pneumatics, hydraulics, &c.

2. That which does not extend to sensible distances. Such is found to obtain in the minute particles of which bodies are composed, attracting each other at or extremely near the point of contact, with forces often much superior to that of gravity, but which at any distance decrease much faster than the power of gravity. This power is generally called the attraction of cohesion, as being that by which the atoms or insensible particles of bodies are united into sensible masses.

This latter kind of attraction claims Sir Isaac Newton for its discoverer; as the former does for its improver. The laws of motion, percussion, &c, in sensible bodies, under various circumstances, as falling, projected, &c, ascertained by the later philosophers, do not reach those more reclusive, intestine motions in the component particles of the same bodies, on which the changes of the texture, colour, properties, &c, depend. So that our philosophy, if it were only founded on the principle of gravitation, and even carried as far as this would lead us, would still be deficient.

But besides the common laws of sensible masses, the minute parts they are composed of are found subject to some others, which have but lately been noticed, and are even yet imperfectly known. Newton himself, to whose happy penetration we owe the hint, is satisfied with establishing that there are such motions in the minima naturae, and that they flow from certain powers or forces, not reducible to any of those in the great world. He shows that, by virtue of these powers, "the small particles act on one another even at a distance; and that many of the phenomena of nature result from this action. Sensible bodies, we have already observed, act on one another several ways; and as

we thus perceive the tenor and course of nature, it appears highly probable that there may be other powers of the like kind; nature being always uniform and consistent with herself." Those just mentioned, reach to sensible distances, and by that means have been observed by vulgar eyes; but there may be others which reach to such small distances as have hitherto escaped observation; and it is probable electricity may reach to such distances, even without being excited by friction."

The great author just mentioned proceeds to confirm the reality of these suspicions by a great number of phenomena and experiments, which plainly argue such powers and actions between the particles, for example of salts and water, oil of vitriol and water, aquafortis and iron, spirit of vitriol and saltpetre, and most other chemical operations. He also shows, that these powers, &c, are unequally strong between different bodies; stronger, for instance, between the particles of salt of tartar and those of aquafortis than those of silver, between aquafortis and lapis calaminaris than iron, between iron and copper than silver or mercury. Thus spirit of vitriol acts on water, but more on iron or copper, &c. And the other experiments are innumerable which countenance the existence of such principle of attraction in the particles of matter.

These actions, by virtue of which the particles of the bodies above-mentioned tend towards each other, the author calls by a general indefinite name, attraction; a name equally applicable to all actions by which distant bodies tend towards each other, whether by impulse, or by any other more latent power: and hence he accounts for an infinity of phenomena which would be otherwise inexplicable from the principle of gravity.

"Thus," adds Newton, "will nature be found very conformable to herself, and very simple; performing all the great motions of the heavenly bodies by the attraction of gravity, which intercedes those bodies, and almost all the small ones and their constituent parts, by some other attractive power diffused through their particles. Without such principles, there could have been no such thing as motion; and without the continuance of it, motion would soon perish, there being otherwise a great decrease or diminution of it, which is only supplied by these active principles."

It need not be said how unjust it was, in the generality of foreign philosophers, to declare against a principle which furnishes so beautiful a view, for no other reason but because they could not conceive how one body should act on another at a distance. It is indeed true, that philosophy allows of no action but what is by immediate contact and impulsion; for how can a body exert any active power where it does not exist? Yet we see effects, without perceiving any such impulse; and where effects are observed, there must exist causes, whether we perceive them or not. But we may contemplate such effects, without entering into the consideration of the causes, as indeed it seems the business of a philosopher to do: for to exclude a number of phenomena which we see, would be to leave a great chasm in the history of nature; and to argue about actions which we do not see, would be to raise castles in the air. It follows therefore, that the phenomena of attraction are matter of physical consideration, and as such entitled to a share in the system of physics; but that their causes will only become so when they become sensible, that is when they appear to be the effect of some other higher causes;

for a cause is no otherwise seen than as itself is an effect, so that the first cause must needs be always invisible; we are therefore at liberty to suppose the causes of attractions what we please, without any injury to the effects. The illustrious author himself seems to be a little indetermined as to the causes; inclining sometimes to attribute gravity to the action of an immaterial cause (*Optics*, p. 343, &c.) and sometimes to that of a material one, *Ib.* p. 325.

In his philosophy, the research into causes is the last thing, and never comes under consideration till the laws and phenomena of the effect be settled; it being to these phenomena that the cause is to be accommodated. The cause even of any, the grossest and most sensible action, is not adequately known. "How impulse or percussion itself produces its effects, that is, how motion is communicated from one body to another, or by what agency it is continued after it is communicated, confounds the deepest philosophers. Yet impulse is received not only into philosophy, but into mathematics; and accordingly the laws and phenomena of its effects make the chief part of common mechanics.

The other species of attraction, therefore, in which no impulse is observable, when their phenomena are sufficiently ascertained, have the same title to be promoted from physical to mathematical consideration; and this without any previous inquiry into their causes, to which our conceptions may not be proportionate.

Our great philosopher, then, far from adulterating science with any thing foreign or metaphysical, as many have reproached him with doing, has the glory of having thrown every thing of this kind out of his system, and of having opened a new source of more sublime mechanics, which, duly cultivated, might be of far greater extent than all the mechanics yet known: it is hence therefore that we must expect to learn the manner of the changes, productions, generations, corruptions, &c, of natural things; 'with all that scene of wonders opened to us by the operations of chance.'

Some of our own countrymen have prosecuted the discovery with laudable zeal. Dr. Keil particularly has endeavoured to deduce some of the laws of this new action, and applied them in resolving several of the more general phenomena of matter, as cohesion, fluidity, elasticity, softness, fermentation, coagulation, &c: and Dr. Freud, seconding his endeavours, has made a farther application of the same principles, to account for almost all the phenomena that chemistry presents. So that some philosophers are inclined to think that the new mechanics should seem already raised to a complete science, and that nothing now can occur but what we have an immediate solution of, from the principles of attractive forces.

But this seems a little too precipitate: a principle so fertile should have been further explained; its particular laws, limits, &c, more industriously detected and laid down, before we had proceeded to the application. Attraction in the gross is so complex a thing, that it may solve a thousand different phenomena alike. The notion is but one degree more simple and precise than action itself; and, till its properties be more fully ascertained, it were better to apply it less, and study it more. It may be added, that some of Newton's followers have been charged with falling into that error which he industriously avoided, viz, of considering attraction as a cause or active property in bodies, not merely as a phenomenon or effect.

Certain attempts have lately been made to assign the probable or possible cause of gravitation, but too absurd to merit more particular notice.

For the laws, properties, &c, of the different kinds of attraction, see their particular articles, COHESION, GRAVITY, MAGNETISM, &c.

ATTRACTION, *Centre of.* See CENTRE of Attraction.

ATTRACTION of Mountains. This is but a late discovery, and must be esteemed a complete confirmation of the Newtonian theory of universal gravitation. According to that system, an attractive power is exerted, not only between those large masses of matter the sun and planets, but likewise between all comparatively smaller bodies, and even between the smallest particles that compose them. Agreeably to this hypothesis, a heavy body, which gravitates or tends toward the centre of the earth, ought likewise, though in a less degree, to be attracted and to tend laterally towards a neighbouring mountain on the earth's surface. So that, a plumb-line, for instance, of a quadrant, hanging near such a mountain, ought to be drawn a little aside, from the perpendicular direction, in consequence of the attractive power of the quantity of matter, of which it is composed; acting in a direction different from that exerted by the whole mass of matter in the earth, and with proportionally inferior degree of force.

Though Sir Isaac Newton had long ago hinted at an experiment of this kind, and had remarked, that "a mountain of an hemispherical figure, 3 miles high, and 6 broad, would not by its attraction draw the plumb-line 2 minutes out of the perpendicular;" yet no attempt to ascertain this matter by actual experiment was made, till about the year 1738; when the French academicians, particularly Messrs. Bouguer and Condamine, who were sent to Peru to measure a degree of the meridian at the equator, attempted to discover the attractive power of Chimborazo, a mountain in the province of Quito. According to their observations, made under unfavourable circumstances, that mountain exerted an attraction equal to $8'$. Though this experiment was not perhaps sufficient to prove satisfactorily even the reality of an attraction, much less the precise quantity of it; yet it does not appear that any steps had been since taken to repeat it.

In the year 1772, the astronomer royal, Dr. Maskelyne, made a proposal for this purpose to the Royal Society: and in 1774, he was deputed to make the trial, accompanied with proper assistants, and provided with accurate instruments. The mountain Schellallien, situated nearly in the centre of Scotland, was chosen as the most proper then found in this island. The observations were made by observing the meridian zenith distances of some fixed stars near the zenith, by means of a zenith sector of 10 feet radius; first on the south, and then on the north side of the hill, the greatest length of which was considerably extended in the east and west direction.

It is plain, that if the mass of matter in the hill should exert any sensible attraction, it would cause the plumb-line of the sector, through which the observer viewed a star in the meridian, to deviate from its perpendicular situation, and would attract it contrarywise at the two opposite stations, thus doubling the effect. On the south side the plumbet would be drawn to the northward, by the attractive power of the hill placed on the north side of it; and on the north side, a contrary and equal deflection of the plumbet would take place, by the like attraction of the hill, now to the southward of it. The apparent zenith di-

stances of the stars must be affected contrarywise; those being increased at the one station, which were diminished at the other; and the correspondent quantities of the deflection of the plumb-line must give the observer the sum of the contrary attractions of the hill, acting on the plumb-line at the two stations; and the half of which will of course indicate the attractive power of the hill.

The various operations requisite for this experiment lasted about 4 months; and from them it appears, that the sum of the two contrary attractions of the hill, in the two temporary observatories, which were successively fixed half way up the hill (where however the effect of the attraction would not be the greatest), was found to be $11''6$; the half of which therefore, or $5''8$, is the mean attraction of the mountain, at that height.

The inferences drawn from these experiments may be reduced to the following:

1. It appears that the mountain Schohallien exerts a sensible attraction; therefore, by the rules of philosophy, we are to conclude, that every mountain, and indeed every particle of the earth, is endowed with the same property, in proportion to its quantity of matter.

2. The law of the variation of this force, in the inverse ratio of the squares of the distances, as laid down by Sir Isaac Newton, is also confirmed by this experiment. For, if the force of attraction of the hill, had been only to that of the earth, as the matter in the hill is to that in the earth, and had not been greatly increased by the near approach to its centre, the attraction of it must have been wholly insensible. But now, by only supposing the mean density of the earth to be double of that in the hill, which seems very probable from other considerations, the attraction of the hill will be reconciled to the general law of the variation of attraction, in the inverse duplicate ratio of the distances, as deduced by Sir Isaac Newton from the comparison of the motion of the heavenly bodies, with the force of gravity at the surface of the earth; and the analogy of nature will be preserved.

3. We may now therefore be allowed to admit this law, and to acknowledge, that the mean density of the earth is about double of that at the surface; and consequently that the density of the internal parts of the earth, is much greater than near the surface. Hence also, the whole quantity of matter in the earth, will be at least as great again, as if it had been all composed of matter of the same density with that at the surface; or will be about 4 or 5 times as great as if it were all composed of water. This conclusion is totally contrary to the hypothesis of some naturalists, who suppose the earth to be only a large hollow shell of matter; supporting itself from the property of an arch, with an immense vacuity in the midst of it. But, were that the case, the attraction of mountains, and even smaller inequalities in the earth's surface, would be very great, contrary to experiment, and would affect the measures of the degrees of the meridian much more than we find they do; and the variation of gravity, in different latitudes, in going from the equator to the poles, as found by pendulums, would not be near so regular as experiments have shown it to be.

4. As mountains are, by these experiments, found capable of producing sensible deflections in the plumb-lines of astronomical instruments; it becomes a matter of great importance, in the mensuration of meridional degrees, either to choose places where the irregular attractions of the elevated parts may be small; or where, by their situation,

they may compensate or counteract each other's effects. See Philos. Trans. vol. 65; or my Albrig. vol. 13, p. 702.

Besides what is above related of this grand experiment, and its results, as it was necessary, so a great deal more was done, than what yet appears by that account. For, though the experiment showed the quantity of deviation in the plumb-line, from its due position, to be $5''8$, and thereby proved the fact of the universal attraction or gravitation of matter, yet this was all that it proved; for as to the mean density of the whole matter in the earth, as above noticed, much more remained to be done, what is there said having been partly from anticipation by a near guess, or rather from the results of accurate calculations which I was at that very time employed in making, and which results I was in the habit of communicating to Dr. Maskelyne, while he was composing his account of the experiment. In fact, to deduce from the experiment the real mean density of the earth, was, from the first projecting of the experiment, considered as a very important part of the business; and in order to this, it was necessary to procure a very minute and correct survey and measurement of the mountain, from which to calculate theoretically the effect of the attraction of every particle of matter contained in its composition. Accordingly, Dr. Maskelyne, with his assistants, made accurate measurements of the hill, with numerous sections, both horizontal and vertical; by means of which, an exact model of it could be made, and the distance and position of every point in it could be ascertained. This survey Dr. M. brought to the committee of the R. Soc. along with the observations of the plumb-line before mentioned; but he declined undertaking the laborious calculations of the attractions of the matter in the hill, which were necessary to show the real mean density of the earth; calculations which would probably occupy four times as much labour and time as had been employed in making the experiment and survey.

Accordingly, at the request of the Royal Society, I undertook this arduous task, and, after about a year's labour, delivered to that body an account of my computations and results, which gave universal satisfaction; which account was printed in the 68th volume of the Philos. Trans. It has also been printed at large in the 2d volume of my Tracts, where it is proved that the mean density of the whole earth is near 5 times the density of water, or almost double the density of the rocks near the earth's surface.

ATTRITION, the striking or rubbing of bodies against one another, so as to throw off some of their superficial particles; such as the grinding and polishing of bodies. Or simply the act of rubbing: as when amber and other electric bodies are rubbed, to make them attract, or emit their electric force.

ATWOOD (GEORGE) F. R. S. a celebrated mathematician and philosopher, was educated at Westminster school; after which he studied at Trinity college, Cambridge, where he was afterwards for some time a tutor, and many years fellow of that college. He was very celebrated also for his courses of lectures, on several branches of experimental philosophy, which he read in the university, with neat illustrations by means of a large and excellent collection of instruments; several of which were of his own contrivance; particularly a very ingenious one, exhibiting the theories respecting the rectilinear motion of bodies which are acted on by constant forces. Of these lectures, he published a very neat Syllabus; also, in 1784, he published, in one large volume in 8vo, A Treatise on the Rec-

tilinear Motion and Rotation of Bodies; a learned and ingenious work, but not treated in the most simple and perspicuous manner. Mr. A. communicated some learned and ingenious papers to the Royal Society, which were printed in their Transactions: viz. 1. On the Mensuration of a certain Angle. 2. On the Times of Vibration of Watch Balances. 3. The Theory of Floating Bodies. 4. The Stability of Ships: all of them in some degree liable to the like imputation with the foregoing; as well as the two Tracts on the subject of Arches and Bridges, in 1801 and 1804; to him apparently a new study; as most of the properties which occurred to him, though common and well known to other writers, he unfortunately fancied to be new discoveries. The whole composition being indeed strongly indicative of the feeble state of body and mind, in which Mr. A. had lingered during some years before his death; which happened in 1807, at 62 years of age.—The late minister, Mr. Pitt, having been one of Mr. A.'s auditors at Cambridge, gave him, in 1784, it is said, a sinecure place of 500*l.* a-year, which he enjoyed during the remainder of his life. It is also said, that the same minister employed him in financial calculations for the public service, in the latter years of his life, till such time as the declining state of his health rendered him incapable of severe application.

AVANT-FOSS, or Ditch of the Counterscarp, in Fortification, is a wet ditch surrounding the counterscarp, on the outer side, next to the country, at the foot of the glacis. It would not be proper to have such a ditch if it could be laid dry, as it would then serve as a lodgment for the enemy.

AVENPACE, a philosopher among the Saracens that invaded Spain, who flourished in the 12th century, and was a follower of Aristotle. He wrote a commentary on Euclid, as well as philosophical and theological epistles. He was also intimately conversant with the Peripatetic philosophy, and applied it to the illustration of the Islamic system of theology, and to the explanation of the Koran; and on this account he was suspected of heresy, and thrown into prison at Corduba. It is said that he was poisoned at Fez, in the year of the Hegira 533, A.D. 1138; or according to others, 525, A.D. 1130.

AVERROES, or ABEN-ROES, a very subtle Arabian philosopher, who flourished about the end of the 11th century, when the Moors had possession of part of Spain. He was the son of the high priest and chief judge of Corduba or Cordova in Spain; but educated in the university of Morocco, where he was professor, and where he died in 1206, having there studied natural philosophy, medicine, mathematics, law, and divinity. After the death of his father, he enjoyed his posts in Spain, to which was afterward added that of judge of Morocco and Mauritania, where having settled deputies, he returned to his duty in Spain. Notwithstanding he was very rich, and had a large income, his liberality to men of letters in necessity, whether they were his friends or his enemies, kept him always in debt. He was afterwards deprived of these means of emolument, and thrown into prison for heresy, by the vile instigations of his enemies; but the oppressions of the judge who succeeded him, caused him to be restored to his former employments.

This philosopher has been highly celebrated for his personal virtues. Such was his temperance, that he partook only once a day of the plainest food. In his application, he was unremitting and indefatigable; allowing himself

no other recreation in the course of the day than the change of several literary occupations, for those of poetry or history, and spending whole nights in study. In the exercise of forbearance, meekness, and self-command, he was signally exemplary. When a servant employed by an enemy intruded upon him in one of his public lectures, and whispered some abusive language, Averroes, with perfect self-possession, turned round to him, and said, "Well, well;" and proceeded with his business. This servant waited on him next day to implore his pardon for the insult he had offered him. "God forgive thee," said Averroes, "thou hast publicly shown me to be a patient man; and as for thine injury, it is not worthy of notice." He then gave him money, and dismissed him with this admonition; "What thou hast done to me, do not to another." He was extremely fond of the works of Aristotle, and wrote commentaries upon them; whence he was styled the *Commentator*, by way of eminence. He also wrote many other pieces; among which is a work on the Whole Art of Physic; an Epitome of Ptolemy's Almagest, which Vossius dates about the year 1149; also a Treatise of Astrology, which was translated into Hebrew by R. Jacob Ben Samson, and said to be extant in the French regal library. He likewise wrote several poems, and many amatory verses; but these last he destroyed when he grew old. His other poems are lost, except a small piece, in which he says, "that when he was young, he acted against his reason; but that when he was in years, he followed its dictates;" upon which he utters this wish, "Would to God I had been born old, and that in my youth I had been in a state of perfection!" As to religion, his opinions were, that Christianity is absurd; Judaism, the religion of children; Mahometanism, the religion of swine.

AVICENA, AVICENNE, or AVICENES, an eminent writer, who has been accounted the prince of Arabian philosophers and physicians. He was born at Assena, near Bokhara, in 978; and died at Hamadan in 1036, being 58 years of age.

The first years of Avicena were employed on the study of the Belles Lettres and the Koran, and at ten years of age he was perfect master of the hidden senses of that book. Then applying to those of logic, philosophy, and mathematics, he made a rapid progress. After studying under a master the first principles of logic, and the first 5 or 6 propositions of Euclid's elements, he became disgusted with the slow manner of the schools, applied himself alone, and soon accomplished all the rest by the help of the commentators only.

Possessed with an extreme avidity to be acquainted with all the sciences, he studied medicine also. Persuaded that this art consists as much in practice as in theory, he sought all opportunities of seeing the sick; and afterwards confessed that he had learnt more from such experience than from all the books he had read. Being now in his 16th year, and already celebrated for being the light of his age, he determined to resume his studies of philosophy, which medicine, &c., had made him for some time neglect: he spent a year and a half in this painful industry, without ever sleeping a whole night together. At the age of 21, he conceived the bold design of incorporating, in one work, all the objects of human knowledge; which he carried into execution in an Encyclopedia of 20 volumes, to which he gave the title of the Utility of Utilities.

Many wonderful stories are related of his skill in medicine, and the cures which he performed. Several princes

had been taken dangerously ill, and Avicenes was the only one that could discover the cause of their disorders and the mode of curing them. His reputation increased daily, and all the princes of the East desired to retain him in their families, and in fact he passed through several of them. But the irregularities of his conduct sometimes lost him their favour, and threw him into great distresses. His excesses in pleasures, and his infirmities, made a poet say, who wrote his epitaph, that the profound study of philosophy had not taught him good morals, nor that of medicine the art of preserving his own health.

After his death however, he enjoyed so great a reputation, that till the 12th century his works of philosophy and medicine were preferred to those of all his predecessors. Even in Europe his works were the only writings in vogue in the schools. They were very numerous, and various, the titles of which are as follow : 1. Of the Utility and Advantage of the Sciences, in 20 books.—2. Of Innocence and Criminality, 2 books.—3. Of Health and Remedies, 18 books.—4. On the Means of preserving Health, 3 books.—5. Canons of Physic, 14 books.—6. On Astronomical Observations, 1 book.—7. On Mathematical Sciences.—8. Of Theorems, or Mathematical and Theological Demonstrations, 1 book.—9. On the Arabic Language, and its Properties, 10 books.—10. On the Last Judgment, —11. On the Origin of the Soul, and the Resurrection of Bodies.—12. On the end we should propose to ourselves in Harangues and Philosophical Argumentations.—13. Demonstration of the Collateral Lines in the Sphere.—14. Abridgment of Euclid.—15. On Finity and Infinty.—16. On Physics and Metaphysics.—17. On Animals and Vegetables, &c.—18. Encyclopedia, 20 volumes.

AUGUST, the 8th month of the year, containing 31 days. In the ancient Roman calendar it was called *sextillis*, as being the 6th month from March, with which their year began; but changed to its present name by the emperor Augustus, who gave it his own name on account of his having obtained many victories and honours in that month.

A VOIRDUPOIS Weight, a weight used in England for weighing all the larger and coarser kinds of goods; as groceries, cheese, butter, flesh, wool, salt, hops, &c., and all metals except gold and silver. Avoirdupois weight is thus divided, viz.

16 dr. or drams make	1 ounce, marked oz.
16 oz. - - - - -	1 pound, - - lb.
112 lb. - - - - -	1 hundred weight, cwt.
20 cwt. - - - - -	1 ton - - - ton.

The Avoirdupois ounce is less than the Troy ounce, in the proportion of 700 to 708, but the Avoirdupois pound is greater than the Troy pound in the proportion of 700 to 576;

for 1 lb Avoird. is = 7000 grains Troy,
but 1 lb Troy is = 5760 grains Troy,
also 1 oz Avoird. is = 437½ grains Troy,
and 1 oz Troy is = 480 grains Troy.

AURIGA, the *Wagoner*, a constellation in the northern hemisphere, consisting of 14 stars in Ptolemy's catalogue; but in Tycho's, 27; in Hevelius's, 40; and in the Britannic catalogue, 66.

This is one of the 48 old asterisms, mentioned by all the most ancient astronomers. It is represented by the figure of an old man, in posture somewhat like sitting, with a goat and her kids in his left hand, and a bridle in his right.

AURORA, the *morning twilight*; or that faint light

which appears in the morning when the sun is within 18 degrees of the horizon.

AURORA BOREALIS, NORTHERN LIGHT, or *Streamers*; a kind of meteor appearing in the northern part of the heavens, mostly in the winter season, and in frosty weather. It is usually of a reddish colour, inclining to yellow, and sends out frequent coruscations of pale light, which seem to rise from the horizon in a pyramidal undulating form, and shooting with great velocity up to the zenith. It appears often in form of an arch, which is partly bright, and partly dark, but generally transparent. And the matter of it is not found to have any effect on the rays of light, which pass freely through it. Dr. Hamilton observes, that he could plainly discern the smallest speck in the Pleiades through the density of those clouds which formed part of the Aurora borealis in 1763, without the least diminution of its splendour, or increase of twinkling. *Philos. Essays*, p. 106.

Sometimes it produces an Iris. Hence M. Godin judges, that most of the extraordinary meteors and phenomena in the skies, related as prodigies by historians, as battles and the like, may probably enough be reduced to the class of Aurora Boreale. *Hist. Acad. R. Sciente. for 1762*, p. 405.

This kind of meteor never appears near the equator; but it seems is frequent enough towards the south pole, like as towards the north, having been observed there by voyagers. See *Philos. Trans.* No. 461, and vol. 54; also Forster's account of his voyage round the world with Captain Cook, where he describes their appearance as observed for several nights together, in sharp frosty weather, which was much the same as those observed in the north, excepting that they were of a lighter colour.

In the Shetland Isles these phenomena are the constant attendants of clear evenings, and afford great relief to the inhabitants among the gloom of the long winter nights: they are called there the *merry dancers*. The same kind of appearances are also seen in the northern latitudes of Sweden and Lapland, where they are particularly beautiful, and afford light to travellers during the whole night. In Hudson's Bay the aurora borealis diffuses a variegated splendour, which is said to equal that of the full moon. In the north-eastern parts of Siberia, according to the description of Gmelin (*Reise durch Siberien*, vol. 3, p. 135) cited and translated by Dr. Blagden (*Phil. Trans.* vol. 74, pa. 228) those northern lights are observed to begin with single bright pillars, rising in the north, and almost at the same time in the north-east, which, gradually increasing, comprehend a large space of the heavens, rush about from place to place with incredible velocity, and finally almost cover the whole sky up to the zenith, producing an appearance as if a vast tent were expanded in the heavens, glittering with gold, rubies, and sapphire. A more beautiful spectacle cannot be painted; but whoever should see such a northern light for the first time, could not behold it without terror. For, however grand the illumination may appear, it is attended, as I have learnt from the relation of many persons, with as much hissing, crackling, and tumult, as if the largest fire-works were playing off. To describe what they then hear, they make use of the expression "spolochi, chodjat," that is, the raging heat is passing. The hunters who pursue the white and blue foxes in the confines of the icy sea, are often overtaken in their courses by these northern lights; their dogs are then so much frightened, that they will not move, but lie obstinately on the ground till the noise has passed. Commonly clear and

calm weather follows this kind of meteor. I have heard this account, not from one person only, but confirmed by the uniform testimony of many, who have spent part of several years in these very northern regions, and inhabited different countries, from the Yenisei to the Lena; so that no doubt of its truth can remain. This seems, indeed, to be the real birth-place of the aurora borealis.

It seems that meteors of this kind have appeared sometimes more frequently than others. They were so rare in England, or else so little regarded, that none are recorded in our annals since that remarkable one of Nov. 14, 1574, till the surprising aurora borealis of March 6, 1716, which appeared for three nights successively, but by far more strongly on the first; except that five small ones were observed in the year 1707 and 1708. Hence it would seem, that the air, or earth, or both, are not at all times disposed to produce this phenomenon.

The extent of these appearances is also very great: that in March 1716 was visible from the west of Ireland to the confines of Russia and the east of Poland, extending at least near 30 degrees of longitude, and from about the 50th degree in latitude, over almost all the north of Europe; and in all places, at the same time, it exhibited the like wondrous appearances. Father Boscowich has determined the height of an aurora borealis, which was observed by the Marquis of Polini the 16th of December 1737, to have been 825 miles high; and Bergman, from a mean of 30 computations, makes the average height of the aurora borealis amount to 70 Swedish, or 469 English miles. But Euler supposes the height to be several thousands of miles; and Mairan also assigns to them a very elevated region.

Many attempts have been made to determine the cause of this phenomenon. Dr. Halley imagines that the watery vapours, or effluvia, exceedingly rarefied by subterraneous fire, and tinged with sulphureous streams, which many naturalists have supposed to be the cause of earthquakes, may also be the cause of this appearance; or that it is produced by a kind of subtle matter, freely pervading the pores of the earth, and which, entering into it nearer the southern pole, passes out again with a similar force into the æther, at the same distance from the northern. This subtle matter, by becoming more dense, or having its velocity increased, may perhaps be capable of producing a small degree of light, after the manner of effluvia from electric bodies, which, by a strong and quick friction, emit light in the dark, to which sort of light this seems to have a great affinity. Philos. Trans. No. 347. See also Mr. Cotes's description of this phenomenon, and his method of explaining it, by streams emitted from the heterogeneous and fermenting vapours of the atmosphere, in Smith's Optics, p. 69; or my Philos. Trans. Abr. vol. 5, p. 477.

The celebrated M. de Mairan, in an express treatise on the Aurora Borealis, published in 1731, supposes its cause to be the zodiacal light, which, according to him, is no other than the sun's atmosphere: this light happening, on some occasions, to meet the upper parts of our atmosphere about the limits where universal gravity begins to act more forcibly towards the earth than towards the sun, falls into our air to a greater or less depth, as its specific gravity is greater or less, compared with the air through which it passes. See Tract. Phys. et Hist. de l'Aurore Boreale. Suite des Memoires de l'Acad. R. des Scien. 1731. Also Philos. Trans. No. 433.

However, Euler is of a different opinion: he does not think that the aurora borealis is owing to

the zodiacal light, as M. de Mairan supposes, but to particles of our atmosphere, driven beyond its limits by the impulse of the solar light. And on this supposition he endeavours to account for the phenomena observed concerning this light. He supposes the zodiacal light and the tails of comets to be owing to a similar cause.

But from the period that the identity of lightning and the electric matter was determined, philosophers have been naturally led to seek for the explication of aerial meteors in the principles of electricity; and there is now no doubt but most of them, and especially the aurora borealis, are electrical phenomena. Besides the more obvious and known appearances which constitute a resemblance between this meteor and the electric matter by which lightning is produced, it has been observed that the aurora occasions a very sensible fluctuation in the magnetic needle; and that when it has extended lower than usual in the atmosphere, the flashes have been attended with various sounds of rushing and hissing, especially in Russia and the other more northern parts of Europe, as noticed by Sig. Beccaria and M. Messier. Mr. Canton, soon after he had obtained electricity from the clouds, offered a conjecture, that the aurora is occasioned by the flashing of electric fire from positive towards negative clouds at a great distance, through the upper part of the atmosphere, where the resistance is least: and he supposes that the aurora which happens at the time when the magnetic needle is disturbed by the heat of the earth, is the electricity of the heated air above it; and this appears chiefly in the northern regions, as the alteration in the heat of the air in those parts is the greatest. Nor is this hypothesis improbable, when it is considered that electricity is the cause of thunder and lightning; that it has been extracted from the air at the time of the aurora borealis; that the inhabitants of the northern countries observe it remarkably strong when a sudden thaw succeeds very cold severe weather; and that the tourmalin is known to emit and absorb the electric fluid only by the increase or diminution of its heat. Positive and negative electricity in the air, with a proper quantity of moisture to serve as a conductor, will account for this and other meteors, sometimes seen in a serene sky. Mr. Canton has since contrived to exhibit this meteor by means of the Torricellian vacuum, in a glass tube about 3 feet long, and sealed hermetically. When one end of the tube is held in the hand, and the other applied to the conductor, the whole tube is illuminated from end to end, and continues luminous without interruption for a considerable time after it has been removed from the conductor. If, after this, it be drawn through the hand either way, the light will be remarkably intense through the whole length of the tube; and though a great part of the electricity be discharged by this operation, it still flashes at intervals, when held only at one extremity, and kept quite still; but if at the same time it be grasped by the other hand in a different place, strong flashes of light dart from one end to the other; and these continue 24 hours or more, without a fresh excitation. Sig. Beccaria conjectures that there is a constant and regular circulation of the electric fluid from north to south; and he thinks that the aurora borealis may be this electric matter performing its circulation in such a state of the atmosphere as renders it visible, or approaching nearer than usual to the earth: though probably this is not the mode of its operation, as the meteor is observed in the southern hemisphere with the same appearances as in the northern. Dr. Franklin

supposes, that the electric fire discharged into the polar regions, from many leagues of vaporised air raised from the ocean between the tropics, accounts for the aurora borealis; and that it appears first, where it is first in motion, namely, in the most northern part; and the appearance proceeds southward, though the fire really moves in the opposite direction. Franklin's Exper. and Obs. 1769, pa. 49. Philos. Trans. vol. 48, pa. 358, 784; Ib. vol. 51, pa. 403. Lettere dell' Elettricismo, pa. 269; or Priestley's Hist. of Electricity. See also an ingenious solution of this phenomenon, on the same principles, by Dr. Hamilton, in his Philos. Essays. Mr. Kirwan (in the Transactions of the Royal Irish Academy, ann. 1788), has some ingenious remarks on the aurora borealis et australis. He gives his reasons for supposing the rarefaction of the atmosphere in the polar regions to proceed from them, and these from a combustion of inflammable air caused by electricity. He observes, that after an aurora borealis the barometer commonly falls, and high winds from the south generally follow.

To the same purpose it is observed by Mr. Wynn (Phil. Trans. vol. 73), that the appearance of an aurora borealis is a sure indication of a hard gale of wind from the south or south-west. This occurred without fail in 23 instances; and he thinks that the splendor of these phenomena will enable the observer to form some judgement concerning the ensuing tempest. If the aurora is bright, the gale will come on within 24 hours, but will be of no long duration: if the light be faint and dull, the gale will be less violent, and longer in gathering, but will continue longer. His observations were made in the English Channel, where such winds are very dangerous; and, by attending to the aurora, he says, that he often escaped, when others were nearly shipwrecked. Observations of this kind would serve to lessen the dangers of navigation.

M. Libes has suggested a new theory, in his Nouv. Dict. de Physique, which, it seems, is adopted by most of the northern philosophers. In his opinion, electric light is not the cause of the aurora borealis; nor has electricity itself any further influence on their existence, than as it fixes the aërial substances, whose combination occasions the meteor. This philosopher's theory is founded on the following principles:—

1. If we excite the electric spark in a mixture of azotic and oxygen gas, there will result nitric acid, or nitrous acid, or nitrous gas, according to the relation that subsists between the gases which compose the mixture.

2. Nitric acid, when exposed to the sun, assumes more colour and volatility. M. Libes placed a receiver over a salver containing nitric acid, and exposed to the action of the solar rays. Some minutes after, the acid appeared coloured, and the receiver filled with red and volatile vapours, which were sustained in it a long while, and diffused a light similar to that of the aurora borealis.

3. In flasks which contain nitrous acid, a ruddy and volatile vapour is always perceived above the vapour.

4. Nitrous gas, in contact with atmospheric air, exhales ruddy vapours, which fly off into the atmosphere.

5. The hydrogen, which is disengaged from the earth's surface, rises, till it occupies, in the higher regions of the atmosphere, a place determined by its specific gravity.

6. The solar heat has very little activity in the polar regions.

These several principles rest on observations and experiments made with great exactness, and most of them too

VOL. I.

well known to need being here described. Now it is plain, from a simple combination of these facts, 1st, that the production of hydrogen must be next to nothing in the polar regions; 2dly, that the higher regions of the polar atmosphere contain very little if any hydrogen; 3dly, that whenever there is a re-establishment of equilibrium of the electric fluid in the polar atmosphere, this fluid can only find in its passage a mixture of azot and oxygen; 4thly, that the electric spark ought to fix and combine these gaseous substances; 5thly, that from this combination must result a production of nitrous acid, or of nitric acid, or of nitrous gas, according to the relation subsisting between the oxygen and azot, that constitute the mixture; 6thly, that the production of either of those acids, or of the gas, will give birth to red and volatile vapours, whose elevation in the atmosphere will form the meteor known by the name of the aurora borealis. After removing some general objections to these preliminary notions, M. Libes then applies them to the phenomena as generally observed of that meteor.

AURUM FULMINANS, a preparation from gold, which being thrown into the fire, it explodes with a violent noise like thunder. The matter is produced by dissolving gold in aqua regia, and precipitating the solution by oil of tartar per deliquitum, or volatile spirit of sal ammoniac. The powder being washed in warm water, and dried to the consistence of a paste, is afterwards formed into small grains of the size of hempseed.

It is inflammable, not only by fire, but also by a gentle warmth; and gives a report much louder than that of gunpowder. A single grain laid on the point of a knife, and lighted at a candle, explodes with a greater report than a musket: and a scruple of this powder, it is said, acts more loudly than half a pound of gunpowder; and yet it is said that, by mixture, it does not increase the elastic force of fired gunpowder. Dr. Black attributes the increase of weight, and also the explosive property of this powder, to adhering fixable air.—This is a very dangerous preparation, and should be used with great caution.

AUSTRAL, the same with Southern. Thus, Austral signs, are the last 6 signs of the zodiac; and are so called because they are on the south side of the equinoctial.

AUSTRALIS CORONA. See **CORONA AUSTRALIS**.

AUSTRALIS PISCIS, the Southern Fish, is a constellation of the southern hemisphere. See **PISCIS AUSTRALIS**.

AUSTRIACA SYDERA, in Astronomy, a name ascribed by Maupertuis to the spots in the sun, as supposing them to be small stars between the sun and us.

AUTOLYCUS, a Greek mathematician and astronomer, of Pitane, in Æolia, who flourished about 320 years before Christ. He was preceptor in mathematics to Arcessalus, who was also a disciple of Theophrastus, the successor of Aristotle. That he was eminent in mathematical learning, appears from two of his works that are extant; viz. a treatise On the Moveable Sphere, published by Dasypodius, in Greek and Latin, Svo, at Strasburg, in 1572; and in a Latin translation, in the Synopsis Mathematica of Mersennus, published in 4to, at Paris, in 1642; and also a treatise On the Rising and Setting of the Stars, edited with the former work by Dasypodius. Diog. Laert. Vit. Arcessil. Fabr. Bib. Græc. tom. 2, p. 89. Montucla Hist. Mathem. I tom. p. 192.

AUTOMATON, a seemingly self-moving machine; or one so constructed, by means of weights, levers, pulleys, springs, &c, as to move for a considerable time as if it

2 C

were endowed with animal life. And according to this description, clocks, watches, and all machines of that kind are automata.

It is said, that Archytas of Tarentum, 400 years before Christ, made a wooden pigeon that could fly; that Archimedes also made such-like automata; that Regiomontanus made a wooden eagle that flew forth from the city, met the emperor, saluted him, and returned; also, that he made an iron fly, which flew out of his hand at a feast, and returned again after flying about the room; that Dr. Hooke made the model of a flying chariot, capable of supporting itself in the air. Many other surprising automata we have been eye-witnesses of, in the present age: thus, we have seen figures that could write, and perform many other actions in imitation of animals: M. Vaucanson made a figure that played on the flute; the same gentleman also made a duck, which was capable of eating, drinking, and imitating exactly the voice of a natural one; and, what is still more surprising, the food it swallowed was evacuated in a digested state, or considerably altered on the principles of solution; also the wings, viscera, and bones, were formed so as strongly to resemble those of a living duck; and the actions of eating and drinking showed the strongest resemblance, even to the muddling the water with its bill. M. Le Droz de la Chaux de Fonds, in the province of Neufchâtel, has also executed some very curious pieces of mechanism; one was a clock, presented to the king of Spain, which had, among other curiosities, a sheep that imitated the bleating of a natural one; and a dog watching a basket of fruit, that barked and snarled when any one offered to take it away; besides a variety of human figures, exhibiting motions truly surprising. But all these seem to be inferior to M. Kempell's chess-player, which may truly be considered as the greatest masterpiece in mechanics that ever appeared in the world. "So it certainly would have been," said my esteemed friend, Thos. Collinson, esq. (nephew of the late ingenious Peter Collinson, esq. F. R. S.) had its scientific movements depended merely on mechanism. "Being slightly acquainted with M. Kempell when he exhibited his chess-playing figure in London, I called on him about five years since at his house at Vienna (another gentleman and myself being then on a tour on the continent). The baron (for I think he is such) showed me some working models which he had lately made—among them an improvement on Arkwright's cotton-mill, and also one which he thought an improvement on Boulton and Watt's last steam-engine. I asked him after a piece of speaking mechanism which he had shown me when in London. It spoke as before, and I gave the same word as I gave when I first saw it, *Exploitation*, which it distinctly pronounced with the French accent. But I particularly noticed, that not a word passed about the chess-player; and of course I did not ask to see it. In the progress of the tour I came to Dresden, where, becoming acquainted with Mr. Eden, our envoy there, by means of a letter given me by his brother, lord Auckland, who was ambassador when I was at Madrid, he obligingly accompanied me in seeing several things worthy of attention. And he introduced my companion and myself to a gentleman of rank and talents, named Joseph Friedrich Freyhere, who seems completely to have discovered the vitality and soul of the chess-playing figure. This gentleman courteously presented me with a treatise he had published, dated at Dresden, Sept. 30, 1789, explaining its principles, accompanied

with curious plates neatly coloured. This treatise is in the German language; and I hope soon to get a translation of it. A well-taught boy, very thin and small of his age (sufficiently so that he could be concealed in a drawer almost immediately under the chess-board,) agitated the whole. Even after this abatement of its being strictly an automaton, much ingenuity remains to the contriver.—This discovery at Dresden accounts for the silence about it at Vienna; for I understand, by Mr. Eden, that Mr. Freyhere had sent a copy to Baron Kempell: though he seems unwilling to acknowledge that Mr. F. has completely analysed the whole.

"I know that long and uninteresting letters are formidable things to men who know the value of time and science; but as this happens to be upon the subject, forgive me for adding one very admirable piece of mechanism to those you have touched upon. When at Gueeva, I called upon Droz, son of the original Droz of la Chaux de Fonds, where I also was. He showed me an oval gold snuff-box, about (if I recollect right) 4 inches and a half long, by 3 inches broad, and about an inch and a half thick. It was double, having an horizontal partition; so that it may be considered as one box placed on another, with a lid, of course, to each box: one contained snuff—in the other, as soon as the lid was opened, there rose up a very small bird, of green enamelled gold, sitting on a gold stand. Immediately this minute curiosity wagged its tail, shook its wings, opened its bill of white enamelled gold, and poured forth, minute as it was (being only three quarters of an inch from the beak to the extremity of the tail) such a clear melodious song, as would have filled a room of 20 or 30 feet square with its harmony. Droz agreed to meet me at Florence; and we visited the Abbé Fontana together. He afterwards joined me at Rome, and exhibited his bird to the pope and the cardinals in the Vatican palace, to the admiration, I may say, to the astonishment, of all who saw and heard it."

Another extract from a second letter on the same subject, by Mr. Collinson, is as follows: "Permit me to speak of another automaton of Droz's, which several years since he exhibited in England; and which, from my personal acquaintance, I had a commodious opportunity of particularly examining. It was a figure of a man, I think, the size of life. It held in its hand a metal style; a card of Dutch vellum being laid under it. A spring was touched, which released the internal clock-work from its stop, when the figure immediately began to draw. Mr. Droz, happening once to be sent for in a great hurry to wait upon some considerable personage at the west end of the town, left me in possession of the keys, which opened the recesses of all his machinery. He opened the drawing-master himself, wound it up, explained its leading parts, and taught me how to make it obey my requirements, as it had obeyed his own: Droz then went away. After the first card was finished, the figure rested. I put a second; and so on, to five separate cards, all different subjects; but five or six was the extent of its delineating powers. The first card contained, I may truly say, elegant portraits and likenesses of the king and queen, facing each other; and it was curious to observe with what precision the figure lifted up his pencil, in the transition of it from one point of the draft to another, without making the least slur whatever: for instance, in passing from the forehead to the eye, nose, &c. I have the cards now by me, &c., &c."

To the preceding account of such surprising accounts of automata, may be added, that we have lately seen exhibited at Spring-Gardens, in London, by a Mr. Malietard, similar and other such mechanical contrivances; viz, the singing-bird, and the figure of a young man that wrote many words and lines, and drew very neatly several figures as above described. There were also several others, equally curious; as a tumbling figure, which performed surprising evolutions about a horizontal, wire; also a spider resembling a living one, and which crept all over the table; and the musical lady, being one that much resembled life, by its motions and respirations, &c, and naturally performing some fine pieces on the piano-forte, &c.

AUTUMN, the third season of the year, when the harvest and fruits are gathered in. This begins at the descending equinox, which, in the northern hemisphere, is when the sun enters the sign *Libra*, or about the 22d day of September; and it ends, when winter commences, about the same day in December.

AUTUMNAL, something belonging to autumn. Thus, **AUTUMNAL Equinox**, the time when the sun enters the descending point of the ecliptic, where it crosses the equinoctial; and is so called, because the nights and days are then equal.

AUTUMNAL Point, the point of the ecliptic answering to the autumnal equinox.

AUTUMNAL Signs, are the signs *Libra*, *Scorpio*, *Sagittarius*, through which the sun passes during the autumn.

AUZOUT, or **Azout**, (**ADRIAN**), a French mathematician of the 17th century, and one of the earliest members of the Academy of Sciences at Paris, was born at Rouen, and died in 1693. Some have ascribed to him the honour of having invented the micrometer; but he is more justly entitled to the praise of having contributed to the improvement of it, in pursuance of the ideas suggested by M. Huygens, and the Marquis of Malvasia. He published a treatise on this subject in 1667, which was afterwards inserted in the Memoirs of the Academy for 1693, tom. 6. Auzout was also concerned with M. Picard in the important discovery of the method of applying the telescope to the quadrant, which has been highly useful to astronomers. He published An Ephemeris of the Comet of 1665; also, A Letter to the Abbé Charles on the Observations of Campanie, in 1665; and some Remarks on the Machine of Hooke, mentioned in the article *Automaton*. These two last pieces are also contained in the 6th volume of the Memoirs of the Academy. Montucla, Hist. Mathem. tom. 2, p. 569—572.

AXIOM, a self-evident truth, or a proposition immediately assented to, when the terms of it are properly understood. Such as, that the whole is greater than its part; that a thing cannot be and not be at the same time; and that any whole is equal to all its parts taken together.

Some axioms are in effect, strictly speaking, no other than identical propositions. Thus, to say that all right angles are equal to each other, is as much as to say, all right angles are right angles; such equality being implied in the very definition, or the very name or term itself.

AXIOM is also an established principle in some art or science. Thus, it is an axiom in physics, that nature does nothing in vain; that effects are proportional to their causes; &c. It is an axiom in geometry, that two things equal to the same thing, are also equal to each other; that if to two equal things equals be added, the sums will be equal. And it is an axiom in optics, that the angle of in-

cidence is equal to the angle of reflection. In this sense also the general laws of motion are called axioms; as, that all motion is rectilinear, that action and reaction are equal, &c.

These particular axioms, it may be observed, do not however immediately arise from any first notions or ideas, but are deduced from certain hypotheses; this is particularly observed in physical matters, wherein, as several experiments contribute to make one hypothesis, so several hypotheses contribute to one axiom.

The axioms of Euclid are general propositions; and so are the axioms of the Newtonian philosophy; but these two kinds of axioms have very different origins. The former appear true upon a bare contemplation of our ideas; whereas the latter are the result of the most laborious induction; and therefore "ought not," as Lord Bacon says, "to be admitted upon conjecture or even upon the authority of the learned; but as they are the general principles and grounds of all learning, they should be canvassed and examined with the most scrupulous attention."

AXE or **AXIS**, in Geometry, the straight line in a plane figure, about which it revolves, to produce or generate a solid. Thus, if a semicircle be moved round its diameter at rest, it will generate a sphere, whose axis is that diameter. And if a right-angled triangle be turned about its perpendicular at rest, it will describe a cone, whose axis is that perpendicular.

AXIS is yet more generally used for a right line conceived to be drawn from the vertex of a figure to the middle of the base. So the

Axis of a circle or sphere, is any line drawn through the centre, and terminated at the circumference, on both sides.

Axis of a cone, is the line from the vertex to the centre of the base.

Axis of a cylinder, is the line from the centre of the one end to that of the other.

Axis of a conic section, is the line from the principal vertex, or vertices, perpendicular to the tangent at that point. The ellipsis and hyperbola have each two axes, which are finite and perpendicular to each other; but the parabola has only one, and that infinite in length.

Transverse Axis, in the Ellipse and Hyperbola, is the diameter passing through the two foci, and the two principal vertices of the figure. In the hyperbola it is the shortest diameter, but in the ellipse it is the longest.

Conjugate Axis, or **Second Axis**, in the Ellipse and Hyperbola, is the diameter passing through the centre, and perpendicular to the transverse axis; and is the shortest of all the diameters, as the transverse axis is the longest.

Axis, of a curve line, is still more generally used for that diameter which has its ordinates at right angles to it, when that is possible. For, like as in the conic sections, any diameter bisects all its parallel ordinates, making the two parts of them on both sides of it equal; and that diameter which has such ordinates perpendicular to it, is an

Axis: So, in curves of the second order, if there be any two parallel lines each meeting the curve in three points; the right line which cuts these two parallels so, that the sum of the two parts on one side of the cutting line, between it and the curve, is equal to the third part terminated by the curve on the other side, then the said line will in like manner cut all other parallels to the former two lines, viz, so that, of every one of them, the sum of the two parts, or ordinates, on one side, will be equal to the

third part or ordinate on the other side. Such cutting line then is a diameter; and that diameter whose parallel ordinates are at right angles to it, when possible, is an Axis. And the same for other curves of still higher orders. Newton, *Enumeratio Linearum Tertii Ordinis*, sect. 2, art. 1.

A X I S, in Astronomy. As the *Axis of the world*, is an imaginary right line conceived to pass through the centre of the earth, and terminating at each end in the surface of the mundane sphere. About this line, as an axis, the sphere, in the Ptolemaic system, is supposed daily to revolve.

Axis of the Earth, is the line connecting its two poles, and about which the earth performs its diurnal rotation, from west to east. This is a part of the axis of the world, and always remains parallel to itself during the motion of the earth in its orbit about the sun, and perpendicular to the plane of the equator.

Axis of a Planet, is the line passing through its centre, and about which the planet revolves.—The Sun, Earth, Moon, Jupiter, Mars, and Venus, it is known from observation, move about their several axes; and the like motion is easily inferred of the other three, Mercury, Saturn, and the Georgian planet.

Axis of the Horizon, Equator, Ecliptic, Zodiac, &c., are right lines passing through the centres of those circles, perpendicular to their planes.

Axis of a Magnet, or Magnetical Axis, is a line passing through the middle of a magnet, lengthwise; in such manner, that however the magnet be divided, provided the division be made according to a plane passing through that line, the magnet will then be cut into two loadstones. And the extremities of such lines are called the poles of the stone.

A X I S, in Mechanics.—The axis of a balance, is the line upon which it moves or turns.

Axis of Rotation, of any solid, is the line about which the body really revolves, when it is put in motion. The impulse given to a homogeneous sphere, in a direction which does not pass through its centre, will cause it to revolve constantly round the diameter, which is perpendicular to a plane passing through its centre, and the line of direction of the impressed force. New forces acting on all its parts, and of which the result passes through its centre, will not change the parallelism of its axis of rotation. Thus it is that the axis of the earth remains always nearly parallel to itself; in its revolution round the sun, without its being necessary to suppose, with Copernicus, an annual motion of the poles of the earth round those of the ecliptic. If the body possess a certain figure, its axis of rotation may change every instant. The determination of these changes, whatever may be the forces acting on the bodies, is one of the most interesting problems of mechanics, respecting hard bodies, on account of its connexion with the precession of the equinoxes, and the libration of the moon. The solution of this problem has led to a curious and very useful result, namely, that in all bodies there exist three axes perpendicular to each other, round which the body may turn uniformly when not solicited by external forces. On this account these axes are properly called the three principal axes of rotation.

Axis of Oscillation, is a line parallel to the horizon, passing through the centre, about which a pendulum vibrates, and perpendicular to the plane in which it oscillates.

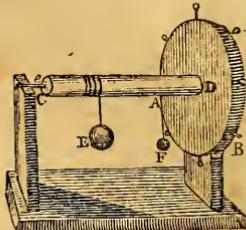

A X I S in Peritrochlo, or *Wheel and axle*, is one of the five mechanical powers, or simple machines; contrived chiefly for the raising of weights to a considerable height, as water from a well, &c. This machine consists of a circle ΔB , concentric with the base of a cylinder, and moveable together with it about its axis CD . This cylinder is called the axis; and the circle, the peritrochium; and the radii, or spokes, which are sometimes fitted immediately into

the cylinder, without any circle, the scytale. About the axis winds a rope, or chain, by means of which great weights are raised by turning the wheel.—The axis in peritrochlo takes place in the motion of every machine, in which a circle may be conceived as described about a fixed axis, concentric with the plane of a cylinder about which it is placed; as in Crane-wheels, Mill-wheels, Capstans, &c.—The chief properties of the Axis-in-peritrochlo, are as follow :

1. If the power F applied in the direction AF a tangent to the circumference, or perpendicular to the spoke, be to a weight E , as the radius of the axis CE is to the radius of the wheel AD , or the length of the spoke; the power will just sustain the weight; that is, the power and the weight will be in equilibrium, when they are in the reciprocal proportion of their distance from the centre.

2. When the wheel moves, with the power and weight; the velocities of their motion, and the spaces passed over by them, will be both in the same proportion as above, namely, directly proportional to their distances from the centre, and reciprocally proportional to their own weights when they are in equilibrium.

3. A power and a weight being given, to construct an axis-in-peritrochlo, by which it shall be sustained and raised. Let the axis be taken large enough to support the weight and power without breaking: then, as the weight is to the power, so make the radius of the wheel to the radius of the axis. Hence, if the power be very small in respect of the weight, the radius of the wheel will be vastly great. For example, suppose the weight 4050, and the power 50; then the radius of the wheel will be 81 times that of the axis; which would be a very inconvenient size. But this inconvenience is obviated by increasing the number of the wheels and axes; making one to turn another, by means of teeth and pinions. And to find the effect of a number of wheels and axes, thus turning one another, multiply together, all the radii of the axes, and all the radii of the wheels, and then it will be, as the product of the former is to the product of the latter, so is the power to the weight. So, if there be 4 wheels and axes, the radius of each axis being 1 foot, and the radius of each wheel 3 feet; then the continual product of all the wheels is $3 \times 3 \times 3 \times 3 = 81$ feet, and that of the axis only 1; therefore the effect is as 81 to 1, or the weight is 81 times the power. And, on the contrary, if it be required to find the diameter of each of four equal wheels, by which a weight of 4050lb shall be balanced by a power of 50lb, the diameter of each axis being 1 foot: dividing 4050 by 50, the quotient is 81, extract the 4th root of 81, or twice

the square root, and it will give 3, for the diameter of the four wheels sought.

Axis of a vessel, is that quiescent right line passing through the middle of it, perpendicular to its base, and equally distant from its sides.

Axis, in Optics.—*Optic axis, or visual axis*, is a ray passing through the centre of the eye, or falling perpendicularly on the eye.

Axis of a lens, or glass, is the axis of the solid of which the lens is a segment. Of the axis of a glass, is the line joining the two vertices or middle points of the two opposite surfaces of the glass.

Axis of Incidence, in Dioptrics, is the line passing through the point of incidence, perpendicularly to the refracting surface.

Axis of Refraction, is the line continued from the point of incidence or refraction, perpendicularly to the refracting surface, along the farther medium.

Azimuth, of the sun, or star, &c, is an arch of the horizon, intercepted between the meridian of the place, and the azimuth or vertical circle passing through the sun or star; and is equal to the angle at the zenith formed by the said meridian and vertical circle. Or it is the complement to the eastern or western amplitude.—The azimuth is thus found by trigonometry;

As radius is to the tangent of the latitude,

So is the tangent of the altitude of the sun or star,

To the cosine of the azimuth from the south, at the time of the equinox.

Azimuth, magnetical, an arch of the horizon contained

between the magnetical meridian, and the azimuth or vertical circle of the object; or its apparent distance from the north or south point of the compass. This is found by observing the sun, or star, &c, with an azimuth compass, when it is 10 or 15 degrees high, either before or after noon.

Azimuth Compass, an instrument for finding either the magnetical azimuth or amplitude of a celestial object. The description and use of this instrument, see under the article **COMPASS**.

Azimuth Dial, a dial whose stile or gnomon is perpendicular to the plane of the horizon.

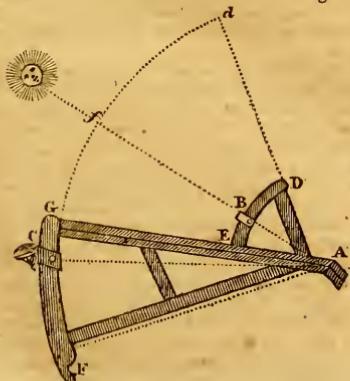

Azimuth, or Vertical Circles, are great circles of the sphere intersecting each other in the zenith and nadir, and cutting the horizon at right angles.—These azimuths are represented by the rhumbs on common sea charts; and on the globe by the quadrant of altitude, when screwed in the zenith. On these azimuths is counted the height of the sun, or stars, &c, when out of the meridian.

Azotic Gas, the same as the phlogisticated air of Scheele and Priestley, or the mephitic air of Lavoisier, or the nitrogen gas of Chaptal, and some other French chemists. This gas was discovered in 1772, by Dr. Rutherford of Edinburgh; and many of its properties were ascertained by Cavendish, Kirwan, and Priestley. It is nearly of the same specific gravity as common air, or perhaps a very little heavier, being indeed only atmospheric air deprived of its oxygen; and hence its noxious quality of presently extinguishing flame and animal life; as in unused wells or cellars, and close places of stagnant air.

B A C

BACK-STAFF, an instrument formerly used for taking the sun's altitude at sea; being so called because the back of the observer was turned towards the sun when he made the observation. It was sometimes called Davis's quadrant, from its inventor Captain John Davis, a Welchman, and a celebrated navigator, who produced it about the year 1590.

This instrument consists of two concentric arches of box-wood, and three vanes: the arch of the longer radius

B A C

is of 30 degrees, and the other of 60 degrees, making between them 90 degrees, or a quadrant: also the vane A at the centre is called the horizon-vane, that on the arch of 60° at B the shade-vane, and that on the other arch at C the sight-vane.

To use the Back-Staff.—The shade-vane is to be set upon the 60 arch, at an even degree with some latitude, less by 10 or 15 degrees than the complement of the sun's altitude is judged to be; also the horizon-vane being put on at A, and the sight-vane on the 30 arch FG, the observer then turns his back to the sun, lifts up the instrument, and looks through the sight-vane, raising or falling the quadrant, till the shadow of the upper edge of the shade-vane fall on the upper edge of the slit in the horizon-vane; and then if he can see the horizon through the said slit, the observation is exact, and the vanes are rightly adjusted: But if the sea appear instead of the horizon, the sight-vane must be moved downward towards F; or if the sky appear, it must be moved upward towards G; thus trying till it comes right: the observer next examines how many degrees and minutes are cut by that edge of the sight-vane that answers to the sight-hole, and to them he adds the degrees cut by the upper edge of the shade vane; the sum of which is the sun's distance from the zenith, or the complement of his altitude; that is, of his upper limb when the superior end of the shade-vane is used in the observation, or of his lower limb when the lower part of that vane is used; therefore in the former case add 16 minutes, the sun's semidiameter, and subtract

16 minutes in the latter case, to give the zenith distance or co-altitude of the sun's centre.

Mr. Flamsteed contrived a glass lens, or double convex, to be placed in the middle of the shade-vane, which throws a small bright spot on the slit of the horizon-vane, instead of the shade; which is a great improvement, if the glass be truly made; for by this means, the instrument may be used in hazy weather, and a much more accurate observation made at all times.

BACON (ROGER), a celebrated English monk of the Franciscan order, was born near Ilchester in Somersetshire, in the year 1214. He commenced his studies at Oxford; whence he removed to the university of Paris, which at that time was esteemed the centre of learning; and where it appears he made such progress in the sciences, that he was esteemed the glory of that university, and was there greatly caressed by several of his countrymen, particularly by Robert Grothead or Grouthead, afterwards bishop of Lincoln, his great friend and patron. Having taken the degree of doctor of divinity, he returned to England in 1240, and took the habit of the Franciscan order, being then about 26 years of age; but according to some he became a monk before he left France. He now pursued his favourite study of experimental philosophy with unremitting ardour and assiduity. In this pursuit, in experiments, he informs us he spent, in the course of 20 years, no less than 2000*l.* in the purchase of instruments and scarce books, an amazing sum in those days, but which was generously furnished him by some of the heads of the university, to enable him the better to pursue his noble researches. By such extraordinary talents and rapid progress in the sciences, which in that ignorant age were so little known to the rest of mankind, while they raised the admiration of the more intelligent few, could not fail to excite the envy of his illiterate fraternity, whose malice against him was the more inflamed by the freedom with which he treated the clergy in his writings, in which he spared neither their ignorance nor their immorality: these therefore found no difficulty in possessing the vulgar with the notion of Bacon's communication with evil spirits. Under this pretence he was restrained from reading lectures to the young students in the university, and at length so closely confined as to be debarred from all intercourse with his friends, and from receiving a necessary supply of food. These efforts of malevolence and cruelty, whatever might have been the real or pretended causes from which they originated, could not however deprive this great man of the esteem and respect to which his distinguished talents and character entitled him. Such was the high opinion entertained by the cardinal-bishop of Sabina, who was the pope's legate in England, of his genius and merit, that he requested from him a complete copy of all his works. As he was restrained, by the prohibition of his own fraternity, from communicating any of his works to any person whatever, he at first declined complying with the cardinal's request; but as soon as he heard that the cardinal-legate was raised to the pontifical dignity, under the name of Clement iv, he signified to him by letter his readiness to perform what his holiness had desired; and the pope assured him of protection against any interference of his own order. Bacon immediately began to collect, arrange, and improve the pieces he had already written: and having digested them into one volume, under the title of "Opus Majus" (the greater work,) he sent it to the pope in the year 1267, by a special messenger, whose

name was John of Paris, and who was his own favourite disciple. This John of Paris was a poor boy, of promising talents, taken by Bacon under his tuition, in order to try by experience the efficacy of his peculiar mode of instruction; and as the result of it he observes, "that there was no room to conceive any high notions of the perfection of human wisdom, when it was possible in a year's time to teach a young man all that, with the utmost industry and application, a zealous inquirer after knowledge was able either to attain or discover in the space of 20 or even 40 years. The pope was so gratified with the present of this learned work, that it procured for Bacon extraordinary favour and encouragement in his studies.

With the life of the enlightened and liberal Clement iv, terminated the tranquillity of this philosopher; for, under the pontificate of Nicholas iii, and with the sanction of his authority, Jerom de Esculo, or de Ascoli, general of the Franciscan order, prohibited the reading of his works, and sentenced him to imprisonment. The pretended cause of this severity has been sought by some writers in certain tracts of Bacon on necromancy, astrology, and alchemy; but the true reason was most probably that dread of innovation, which Bacon's improvements in science caused in the minds of bigoted or interested persons. Bacon continued in prison 10 years; but on the accession of Jerom de Esculo to the papal see, under the name of Nicholas iv, he attempted to conciliate the favour of the pope, by presenting to him a treatise "On the means of avoiding the infirmities of old age." What effect this had on the pope does not appear; it did not at least produce an immediate discharge: however, towards the latter end of his reign, by the interposition of some noblemen, Bacon obtained his liberty; and afterwards spent the remainder of his life in the college of his order, where he died in the year 1294, at 80 years of age, and was buried in the Franciscan church. Such are the few particulars which the most diligent researches have been able to discover concerning the life of this very extraordinary man.

Bacon's printed works are, 1. *Epistola Fratris Rogeri Baconis de Secretis Operibus Artis et Naturæ, et de Nullitate Magie:* Paris, 1542, in 4to. Basil, 1593, in 8vo. 2. *Opus Majus:* London, 1733, in fol.-published by Dr. Jebb. 3. *Thesaurus Chemicus:* Franc. 1603 and 1620. These printed works of Bacon contain a number of essays, which have been considered as distinct books in the catalogue of his writings by Bale, Pitts, &c; but there remain also in different libraries several manuscripts not yet published.

By an attentive perusal of his works, the reader is astonished to find that this great luminary of the 13th century was deeply skilled in all the arts and sciences, and in many of them had made the most important inventions and discoveries. He was, says Dr. Peter Shaw, beyond all comparison the greatest man of his time, and he might perhaps stand in competition with the greatest that have appeared since. It is wonderful, considering the ignorant age in which he lived, how he came by such a depth of knowledge on all subjects. His writings are composed with such just and exquisite observations on nature, that, among all the chemists, we do not know his equal. In his chemical writings, he attempts to show how imperfect metals may be ripened into perfect ones; making, with Geber, mercury the common basis of all metals, and sulphur the cement.

His other physical writings show no less genius and force of mind. In his treatise Of the Secret Works of Art and Nature, he shows that a person perfectly acquainted with the manner observed by nature in her operations, would be able to rival, and even to surpass her. In another piece, Of the Nullity of Magic, he shows with great sagacity and penetration, whence the notion of it sprang, and how weak all pretences to it are. From a perusal of his works, adds the same author, we find Bacon was no stranger to many of the principal discoveries of the present and past ages. The ingredients and effects of gunpowder he was doubtless acquainted with; and thunder and lightning, he tells us, may be produced by art; for though sulphur, nitre, and charcoal, when separate have no sensible effect, yet when mixed together in due proportion, and closely confined, and fired, they yield a loud report. A more precise description of gunpowder cannot be given in words. He also mentions a sort of unextinguishable fire prepared by art; which shows he was not unacquainted with phosphorus; and that he had some notion of the rarefaction of the air, and the structure of an air-pump, is past contradiction. He was the miracle, says Dr. Friend, of the age he lived in, and the greatest genius, perhaps, for mechanical knowledge, that ever appeared in the world since Archimedes. He appears also to have been master of the whole science of optics: he has accurately described the uses of reading-glasses, and shown the way of making them. Dr. Friend adds, that he also describes the camera obscura, and all sorts of glasses, which magnify or diminish any object, or bring it nearer to the eye, or remove it farther off. Bacon says himself, that he had great numbers of burning-glasses; and that there were none ever in use among the Latins, till his friend Peter de Mahara Curia applied himself to the making of them. That the telescope was not unknown to him, appears from a passage where he says, that he was able to form glasses in such a manner, with respect to our sight and the objects, that the rays shall be refracted and reflected wherever we please, so that we may see a thing under what angle we think proper, either near or at a distance, and be able to read the smallest letters at an incredible distance, and to count the dust and sand from the greatness of the angle under which we see the objects; and also that we shall scarce see the greatest bodies near us, on account of the smallness of the angle under which we view them. His skill in astronomy was also very great: he discovered that error which occasioned the reformation of the calendar; one of the greatest efforts, according to Dr. Jebb, of human industry: and his plan for correcting it was followed by pope Gregory XIII, with this variation, that Bacon would have had the correction to begin from the birth of our Saviour, whereas Gregory's amendment reaches no higher than the Nicene council.

BACON (FRANCIS), baron of Verulam, viscount of St. Albans, and lord high chancellor of England under king James I. He was born in 1560, being son of Sir Nicholas Bacon, lord keeper of the great seal in the reign of Queen Elizabeth, by Anne daughter of Sir Anthony Cook, eminent for her skill in the Latin and Greek languages. He gave even in his infancy tokens of what he would one day become; and Queen Elizabeth had many times occasion to admire his wit and talents, and used to call him her young lord keeper. He studied the philosophy of Aristotle at Cambridge; where he made such progress in general literature, that at 16 years of age he had run through the whole circle of the liberal arts as they were then taught,

and even began to perceive those imperfections in the reigning philosophy which he afterwards so effectually exposed, and thence not only overcame that tyranny which checked the progress of true knowledge, but laid the foundation of that free and useful philosophy which has since opened a way to so many glorious discoveries. On his leaving the university, his father sent him to France; where, before he was 19 years of age, he wrote a general view of the state of Europe: but his father dying, he was obliged suddenly to return to England; where he applied himself to the study of the common law, at Gray's-inn. His merit at length raised him to the highest dignities in his profession, namely, those of attorney-general, and lord-high-chancellor. But being of an easy and liberal disposition, his servants took advantage of that temper, and of their situation under him, by accepting presents in the line of his profession. Being abandoned by the king, he was tried by the house of lords, for bribery and corruption, and by them sentenced to pay a fine of 40,000*l.*, and to remain prisoner in the Tower during the king's pleasure. The king however soon after remitted the fine and punishment: but his misfortunes had given him a distaste for public affairs, and he afterwards mostly lived a retired life, closely pursuing his philosophical studies and amusements, during which time he composed the greatest part of his English and Latin works. Though even in the midst of his honours and employments he forgot not his philosophy, but in 1620 published his great work Novum Organum. After some years spent in his philosophical retirement, he died in 1626, being 66 years of age.

The chancellor Bacon is one of those extraordinary geniuses who have contributed most to the advancement of the sciences. He clearly perceived the imperfection of the school philosophy, and pointed out the only means of reforming it, by proceeding in the opposite way, from experiments to the discovery of the laws of nature. Addison has said of him, That he had the sound, distinct, comprehensive knowledge of Aristotle, with all the beautiful light graces and embellishments of Cicero. Mr. Walpole calls him the Prophet of Arts, which Newton was afterwards to develope; and adds, that his genius and his works will be universally admired as long as science exists. He did not yet, said another great man, understand nature, but he knew and pointed out all the ways that lead to her. He very early despised all that the universities called philosophy; and used every exertion in his power that they should not disgrace her by their quiddities, their horrors of a vacuum, their substantial forms, and such-like impertinencies.

He composed two works for perfecting the sciences. The former On the Dignity and Augmentation of the Sciences. In this he shows the state in which they then were, and points out what remains to be discovered for perfecting them; condemning the method employed by Aristotle, of reversing the natural order of things. He here also proposes his celebrated division of the sciences.

To remedy the faults of the common logic, Bacon composed his second work, the New Organ of Sciences, above mentioned. He here teaches a new logic, the chief end of which is to show how to make a good inference, as that of Aristotle's is to make a syllogism. Bacon was 18 years in composing this work, and he always esteemed it as the chief of his compositions.

The pains which Bacon bestowed on the sciences in general, prevented him from making any considerable appli-

cations to any one in particular: and as he knew that natural philosophy is the foundation of all the other sciences, he chiefly endeavoured to give perfection to it. He therefore proposed to establish a new system of physics, rejecting the doubtful principles of the ancients. For this purpose he took the resolution of composing every month a treatise on some branch of physics; and accordingly began with that of the winds; after which he gave that of heat; next that of motion; and lastly that of life and death. But as it was impossible that one man alone could so compose the whole circle of sciences with the same precision, after having given these patterns, to serve as a model for those who might choose to labour on his principles, he contented himself with tracing in a few words the design of four other tracts, and with furnishing the materials, in his *Silva Silvarum*, where he has amassed a vast number of experiments, to serve as a foundation for his new physics. In fact, no one before Bacon understood any thing of the experimental philosophy; and of all the physical experiments which have been made since his time, there is scarcely one that is not pointed out in his works.

This great precursor of philosophy was also an elegant writer, an historian, and a wit. His moral essays are valuable, but are formed more to instruct than to please. There are also many excellent things in his work *On the Wisdom of the Ancients*, in which he has moralized the fables which formed the theology of the Greeks and Romans. He wrote also *The History of Henry the 7th king of England*, by which it appears that he was no less a great politician than a great philosopher.

Bacon had also some other writings, published at different times; the whole of which were collected together, and published at Frankfort, in the year 1665, in a large folio volume, with an introduction concerning his life and writings. Another edition of his works was also published at London in 1740; the enumeration of which is as below:

1. *De Dignitate et Augmentis Scientiarum.*
2. *Novum Organum Scientiarum, sive Judicia vera de Interpretatione Naturae; cum Parasceve ad Historiam Naturalem et Experimentalē.*
3. *Phænomena Universi, sive Historia Naturalis et Experimentalis de Ventis; Historia Densi et Rari; Historia Gravis et Levis; Historia Sympathiae et Antipathiae Rerum; Historia Sulphuris, Mercurii, et Salis; Historia Vitæ et Mortis; Historia Naturalis et Experimentalis de Forma Calidi; De Motus, sive Virtutis activæ variis speciebus; Ratio inveniendi causas Fluxus et Refluxus Maris; &c. &c.*
4. *Silva Silvarum, sive Historia Naturalis.*
5. *Novus Atlas.*
6. *Historia Regni Henrici VII Anglie Regis.*
7. *Sermones Fideles, Ethici, Politici, Oeconomici.*
8. *De Sapientia Veterum.*

BACULÉ, in Fortification, a kind of portcullis, or gate, made like a pit-fall, with a counterpoise, and supported by two great stakes. It is usually made before the corps de garde, near the gate of a place.

BACULOMETRY, the art of measuring either accessible or inaccessible lines, by the help of baculi, staves, or rods. Schwenter has explained this art in his *Geometria Practica*; and the rules of it are delivered by Woflius, in his *Elements*: Ozanam also gives an illustration of the principles of baculometry.

BAILLY (JEAN SYLVAIN), a celebrated French astro-

nomer, historiographer, and politician, was born at Paris the 15th of September 1736, and has figured as one of the greatest men of the age, being a member of several academies, and an excellent scholar and writer. He enjoyed for several years the office of keeper of the king's pictures at Paris. About the year 1762, the theory of Jupiter's satellites became a particular object of his inquiries; and, in the competition for this prize question, he had a formidable rival in La Grange, generally considered as one of the greatest mathematicians in Europe. The results of his investigations were afterwards collected into a treatise, and published in 1 vol. 4to; also in 1766, when it was preceded by a *History of the Astronomy of these Satellites*. In the *Journal Encyclopédique* for May and July 1773, he addressed a letter to M. Bernoulli, astronomer royal at Berlin, on some discoveries relative to these satellites, which he had disputed. In 1768 he published the eulogy of Leibnitz, which obtained the prize at the Academy of Berlin, where it was printed. In 1770 he printed at Paris, in 8vo, the eulogies of Charles the 5th, also of Lecaille, of Leibnitz, and of Corneille. This last had the second prize at the Academy of Rouen, while that of Moliere had the same honour at the French Academy.

M. Bailly was admitted into the Academy as *Adjunct* the 29th of January 1763, and as *Associate* the 14th of July 1770. In 1771 he was a candidate, under the patronage of Buffon, for the office of Secretary; but the interest of Condorcet, and the influence of Dalembert, prevailed in favour of Condorcet. Of the Academic Françoise, he was chosen *Secretary* in 1754; and he was admitted in the following year into the Academy of Inscriptions and Belles Lettres, the only instance since Fontenelle of the same person being at once a member of all the three Academies. In 1775 came out at Paris, in 4to, his *History of the Ancient Astronomy*, in 1 vol.: in 1779 the *History of Modern Astronomy*, in 2 vols.: and in 1787 the *History of the Indian and Oriental Astronomy*, being the 2d vol. of the *Ancient Astronomy*.

M. Bailly's memoirs, published in the volumes of the Academy, are as follow:

Memoir upon the Theory of the Comet of 1759.

Memoir upon the Epoches of the Moon's motions at the end of the 17th century.

First, second, and third Memoirs on the Theory of Jupiter's Satellites; 1763.

Memoir on the Comet of 1762; vol. for 1763.

Astronomical Observations, made at Noslon; 1764.

On the Sun's Eclipse of the 1st of April, 1764.

On the Longitude of Polling; 1764.

Observations made at the Louvre from 1760 to 1764; 1765.

On the cause of the Variation of the Inclination of the Orbit of Jupiter's second Satellite; 1765.

On the Motion of the Nodes, and on the Variation of the Inclination of Jupiter's Satellites; 1766.

On the Theory of Jupiter's Satellites, published by M. Bailly, also according to the Tables of their Motions and of those of Jupiter, published by M. Jeaurat; 1766.

Observations on the Opposition of the Sun and Jupiter; 1768.

On the Equation of Jupiter's Centre, and on some other Elements of the Theory of that Planet; 1768.

On the Transit of Venus over the Sun, the 3d of June 1769; and on the Solar Eclipse the 4th of June the same year; 1769.

In the beginning of the revolution in France, in 1789, M. Bailly took an active part in that business, and was so popular and generally esteemed, that he was chosen the first president of the States General, and of the National Assembly, and was afterwards for two years together the Mayor of Paris; in both which offices he conducted himself with great spirit, and gave general satisfaction.

He soon afterward however experienced a sad reverse of fortune; being accused by the ruling party of favouring the king, he was condemned for incivism and for wanting to overturn the Republic; in consequence he died by the guillotine at Paris, November 12, 1793, at 57 years of age.

BAINBRIDGE (JOHN), an eminent physician, astronomer, and mathematician, was born in 1582, at Ashby-de-la-Zouch, Leicestershire. He studied at Cambridge, and having taken his degrees of Bachelor and Master of Arts, he returned to Leicestershire, where for some years he kept a grammar-school, and at the same time practised physic; employing his leisure hours in studying mathematics, especially astronomy, which had been his favourite science from his earliest years. By the advice of his friends, he removed to London, where he was admitted a fellow of the College of Physicians. His description of the comet which appeared in 1618, greatly raised his character, and procured him the acquaintance of Sir Henry Savile, who, in 1619, appointed him his first professor of astronomy at Oxford. On his removal to this university, he entered a master-commoner of Merton college; the master and fellows of which appointed him junior reader of Linacre's lecture in 1631, and superior reader in 1635. At the age of 40 he began the study of Arabic, with an intention of publishing correct editions of the ancient astronomers. Before completing that work however he died, in the year 1643, at 61 years of age.

Dr. Bainbridge wrote many works, but most of them have never been published; those that were published, were the three following, viz:

1. An Astronomical Description of the late Comet, from the 18th of November 1618, to the 16th of December following; 4to, London, 1619.—This piece was only a specimen of a larger work, which the author intended to publish in Latin, under the title of *Cometographia*.

2. Procli Sphæra, Ptolemaei de Hypothesibus Planetarum liber singularis. To which he added Ptolemy's *Canon Regnorum*. He collated these pieces with ancient manuscripts, and gave a Latin version of them, illustrated with figures: printed in 4to, 1620.

3. Canicularia. A treatise concerning the Dog-star, and the Canicular Days: published at Oxford in 1648, by Mr. Greaves, together with a demonstration of the heliacal rising of Sirius, the dog-star, for the parallel of Lower Egypt. Dr. Bainbridge also undertook this work at the request of Archbishop Usher, but he left it imperfect; being prevented by the breaking out of the civil war, or by death.

There were also several dissertations of his prepared and committed to the press the year after his death, but the edition of them was never completed. The titles of them are as follow:

1st, Antiprognosticon, in quo Martisq; Astrologice, Cœlestium Domorum, et Triplicatum Commentis, magnisq; Saturni et Jovis (cujusmodi anno 1623, et 1643, contigerunt, et vicissimo fere quoque deinceps anno, ratis

VOL. I.

naturæ legibus recurrent) Conjunctionibus innixæ, Vanitas breviter detegitur.

2d, De Meridionorum sive Longitudinum Differentiis inventiendi Dissertatione.

3d, De Stella Veneris Diatriba.

Besides the foregoing, there were several other tracts, never printed, but left by his will to Archbishop Usher; among whose manuscripts they are preserved in the library of the college of Dublin. Among which are the following: 1. A Theory of the Sun. 2. A Theory of the Moon. 3. A Discourse concerning the Quantity of the Year. 4. Two volumes of Astronomical Observations. 5. Nine or ten volumes of Miscellaneous Papers relating to Mathematical Subjicis.

BAKER (THOMAS), a mathematician of some eminence, was born at Ilton in Somersetsshire, in 1625. He entered on his studies at Oxford in 1640, where he remained seven years. He was afterwards appointed vicar of Bishop's-Nymmet in Devonshire, where he lived a studious and retired life for many years, chiefly pursuing the mathematical sciences, of which he gave a proof of his critical knowledge, in the book he published, concerning the general construction of biquadratic equations, by a parabola and a circle; the title of which book at full length is, "The Geometrical Key; or the Gate of Equations unlocked: or a new Discovery of the Construction of all Equations, howsoever affected, not exceeding the 4th degree, viz, of Linears, Quadratics, Cubics, Biquadratics, and the finding of all their Roots, as well False as True, without the use of Mesolabe, Trisection of Angles, without Reduction, Depression, or any other previous preparations, of equations by a circle, and any (and that only) Parabole, &c." 1684, 4to, in English and Latin.

There is some account of this work in the Philos. Trans. an. 1684. And a little before his death, the Royal Society sent him some mathematical queries; to which he returned such satisfactory answers, as procured the present of a medal, with an inscription honourable and respectful. Mr. Baker died at Bishop's-Nymmet, 1690, in the 65th year of his age.

BAKER (HENRY), an ingenious and diligent naturalist, was born in London about the beginning of the 18th century. He was brought up under an eminent bookseller, but being of a philosophical turn of mind, he quitted that line of business soon after the expiration of his apprenticeship, and engaged himself in teaching deaf and dumb persons to speak and write &c, in which occupation, in the course of his life, he acquired a handsome fortune. For his amusement he cultivated various natural and philosophical sciences, particularly botany, natural history, and microscopical subjects, in which he especially excelled, having, in the year 1744, obtained the Royal Society's gold medal, for his microscopical experiments on the crystallizations and configurations of saline particles. He had also various papers published in the Philos. Trans. of the Royal Society, of which he was a worthy member, as well as of the Societies of Antiquaries, and of Arts. He was author of many pieces, on various subjects, the principal of which were, his Treatise on the Water Polype, and two Treatises on the Microscope, viz, *The Microscope made easy*, and *Employment for the Microscope*, which have gone through several editions.

Mr. Baker married Sophia, youngest daughter of the celebrated Daniel Defoe, by whom he had two sons, one

of whom, Henry Erskine Baker, was the author of the first edit. of the little work called, *The Companion to the Play-house*. He terminated an honourable and useful life, at his apartments in the Strand, on the 25th of November 1774, being then upwards of 70 years of age.

BAKER'S CENTRAL RULE, for the Construction of Equations; is a method of constructing all equations, not exceeding the 4th degree, by means of a given parabola and a circle, without any previous reduction of them, or first taking away their second term. See CENTRAL Rule.

BALANCE, one of the six simple powers in mechanics, chiefly used in determining the equality or difference of weight in heavy bodies, and consequently their masses or quantities of matter.

The balance is of two kinds, the ancient and modern. The ancient or Roman balance, called also Statera Romana, or Steelyard, consists of a lever or beam, moveable on a centre, and suspended near one of its extremities. The bodies to be weighed are suspended from the shorter end, and their weight is shown by the division marked on the beam, where the power or constant weight, which is moveable along the lever, keeps the steelyard in equilibrio. This balance is still in common use for weighing heavy bodies.

The modern balance, now commonly used, consists of a lever or beam suspended exactly at the middle, and having scales hung from the two extremities, to receive the weights to be weighed.

In either case the lever is called the jugum or the beam, and its two halves on each side the axis, the brachia or arms; also the line on which the beam turns, or which divides it in two, is called the axis; which when considered with regard to the length of the brachia, is esteemed only a point, and called the centre of the balance, or centre of motion: the extremities where the weights are applied, are the points of application or suspension; the handle by which the balance is held, or by which the whole apparatus is suspended, is called trutina; and the slender part perpendicular to the beam, by which is determined either the equilibrium or preponderancy of bodies, is called the tongue of the balance.

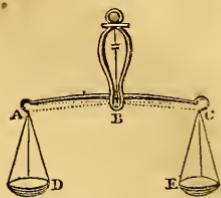

From these descriptions we easily gather the characteristic distinction between the Roman balance and the common one, viz, that in the Roman balance, there is one constant weight used as a counterpoise, the point where it is suspended being varied; but, on the contrary, in the common balance or scales, the point of suspension remains the same, and the counterpoise is varied. The principle of both of them may be easily understood from the general properties of the lever, and the following observations. See LEVER.

The beam ABC, the principal part of the balance, is a lever of the first kind; but instead of resting on a fulcrum, it is suspended by a handle, &c, fastened to its centre of motion B: and hence the mechanism of the balance depends on the same theorems as that of the lever. Consequently as the distance between the centre of motion and the place of the unknown weight, is to the distance between the same centre and the place of the known weight, so is the latter weight to the former. So that the unknown weight is discovered by means of the known one, and their distances from the common centre of motion; viz, if the distances from the centre be equal, then the two weights will be equal also, as in the common balance; but

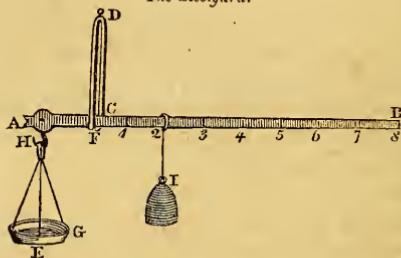

if the distances be unequal, then the weights will also be unequal, and in the very same proportion, alternately, the less weight having so much the greater distance, as in the steelyard.

The Common Balance or Scales.

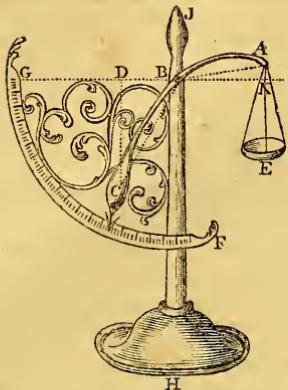

The two brachia AB, BC, should be exactly equal in length, and in weight also when their scales D and E are fixed on their ends; the beam should hang exactly level or horizontal, in the case of an equipoise; for which purpose the centre of gravity of the whole should fall a little below the centre of motion, and but a little, that the balance be sufficiently sensible to the least variation of weight: the friction on the centre should also be as small as possible.

The Steelyard.

Having taken a proper bar of steel AB, tapering at the longer end, and very strong at the other, suspend it by a centre c near the shorter or thicker end, so that it may exactly balance itself in equilibrio, and prepare a constant weight 1 to weigh with: then hang on any weight, as one pound for instance, at the shorter arm, and slide the constant weight backwards and forwards upon the longer arm, till it be just in equilibrio with the former; and there make a notch and number 1, for the place of 1 pound: take off the 1lb, and hang a two pound weight in its stead at the shorter arm; then slide the constant weight back on the longer arm, till the whole come again into a state of equilibrium, making a notch at the place of the constant weight and the number 2, for the place of 2lb. Proceed in the same manner for all other weights, 3, 4, 5, &c; as also for the intermediate halves and quarters, &c, if it be necessary; always suspending the variable weights at the end of the shorter arm, shifting the constant weight so as to balance them, and marking and numbering the places on the longer arm where the constant weight always makes a counterpoise. The use of the steelyard is hence very evident: the thing whose weight is required being suspended by a hook at the short end, move the constant weight backwards and forwards on the longer arm, till the beam is balanced horizontally: then look what notch the constant weight is placed at, and its number will show the weight of the body that was required. DC is the handle and tongue; F the centre of motion; EG a scale sometimes hung on at the end by the hook II.

The Bent-Lever Balance.

This instrument operates by a fixed weight, *c*, increasing in power as it ascends along the arc *HG* of a circle, and pointing by an index to the number or division of the arc which denotes the weight of any body put into the scale at *E*. And thus one constant weight serves to weigh all others, by only varying the position of the arms of the balance, instead of varying the places or points of suspension in the arms themselves.

The Deceitful, or False Balance. This operates in the same manner as the steelyard, and cheats or deceives by having one arm a little longer than the other; though the deception is not perceived, because the shorter arm is made somewhat heavier, so as to compensate for its shortness, by which means the beam of the balance, when no weights are in the scales, hangs horizontal in equilibrio. The consequence of this construction is, that any commodity put in the scale of the longer arm, requires a greater weight in the other scale to balance it; and so the body is fallaciously accounted heavier than it really is. But the trick will easily be detected by making the body and the weight change places, removing them to the opposite scales, when the weight will immediately be seen to preponderate.

The true weight of any thing may however be found out by means of the false balance, in this manner: viz, Weigh the body first in the one scale, next in the other; then take a mean proportional between the two different weights thus indicated, and that will be the true weight required. Thus, suppose the two false weights be $\frac{7}{4}$ and $\frac{5}{4}$; the product of these two is 36, the square root of which, $\frac{6}{2}$, is the true weight. Or, half the sum of the two false weights, $\frac{7}{4}$ and $\frac{5}{4}$, which in this case is $\frac{6\frac{1}{2}}{4}$, will commonly be very near the true weight, though always a very little too much.

Assay-Balance. This is a very nice balance, used in determining the exact weights of very small bodies. Its structure is but little different from the common sort; except that it is made of the best and hardest steel, and made to turn with the smallest weight. For an account of several balances, which have been constructed by different persons for delicate experiments, consult the 66th vol. of the Phil. Trans., also the same work for 1799, part 2. See also Nicholson's Chemistry, chap. 6, and Parkinson's System of Mechanics.

Hydrostistical Balance. This is an instrument for determining the specific gravity of bodies. See HYDROSTASTICAL, and SPECIFIC GRAVITY.

BALANCE, in Astronomy, the same as *Libra*.

BALANCE of a Clock or Watch, is that part which, by its motion, regulates and determines the beats. The circular part of it is called the Rim, and its spindle the Verge; there belong to it also two pallets or nuts, that play in the fangs of the crown-wheel: in pocket-watches, that strong stud in which the lower pivot of the verge plays, and in the middle of which one pivot of the crown-wheel runs, is called the Potence; the wrought piece which covers the balance, and in which the upper pivot of the balance plays, is the cock; and the small spring in the new pocket-watches is called the Regulator.

BALANCE of Forces, in Mechanics. See COMPOUND MOTION.

BALCONY, a projection in the front of a house, or other building, commonly supported by pillars or consoles, and encompassed by a ballustrade.

BALL, any spherical, globular, or round body.

BALL, in the military art, signifies all sorts of bullets for fire-arms, from the pistol up to the largest cannon. Cannon balls are made of cast-iron; but the musket and pistol-balls of lead, as these are both heavier under the same bulk, and do not furrow the barrels of the pieces.

BALL of a Pendulum, is the weight at the bottom of it; and is sometimes, especially in shorter pendulums, called the Bob.

BALLS of Fire, in Meteorology. See FIRE BALLS.

BALLS, in Electricity, invented by Mr. Canton, are two pieces of cork, or pith of elder-tree, nicely turned in a calibre to the size of a small pea, and suspended by very delicate threads. They are used as electrometers, and are of excellent use to discover small degrees of electricity; and to observe its changes from positive to negative, or the reverse; as also to estimate the force of a shock before the discharge, so that the operator shall always be able to tell very nearly beforehand what the explosion will be, by knowing how high he has charged his jars.

BALLISTA, a military engine much used by the ancients for throwing stones, darts, and javelins; it somewhat resembled our cross-bows, but much larger and stronger. The word is Latin, signifying a cross-bow; but is derived from the Greek βαλλω, to shoot, or throw.

Vegetius informs us, that the ballista discharged darts with such violence and rapidity, that nothing could resist their force; and Athenaeus adds, that Agistratus made one of little more than 2 feet in length, that shot darts 500 paces. Authors have often confounded the ballista with the catapulta, attributing to the one what belongs to the other. According to Vitruvius, the ballista was made after divers manners, though all were used for the same purpose: one sort was framed with levers and bars; another with pulleys; some with a crane; and others again with a toothed wheel. Marcellinus describes the ballista thus: A round iron cylinder is fastened between two planks, from which reaches a hollow square beam placed cross-wise, fastened with cords, to which are added screws. At one end of this stands the engineer, who puts a wooden shaft, or arrow, with a large head, into the cavity of the beam; this done, two men bend the engine, by drawing some wheels; when the top of the head is drawn to the utmost end of the cords, the shaft is driven out of the ballista, &c.

The ballista is ranked by the ancients among the sling

kind, and its structure and effect reduced to the principles of that instrument; whence it is called by Hero and others, Funda, and Fundibulus. Gunther calls it Balearica machina, as a sling peculiar to the Balearic islands.—Perrault, in his notes on Vitruvius, gives a new contrivance of a like engine for throwing bombs without powder.

Fig. 1, Plate v, represents the ballista used in sieges, according to Folard: where 2, 2, denote the base of the ballista; 3, 4, upright beams; 5, 6, transverse beams; 7, 7, the two capitals in the upper transverse beam, (the lower transverse beam has also two similar capitals, which cannot be seen in this transverse figure); 9, 9, two posts or supports for strengthening the transverse beams; 10, 10, two skeins of cords fastened to the capitals; 11, 11, two arms inserted between the two strands, or parts of the skeins; 12, a cord fastened to the two arms; 13, darts which are shot by the ballista; 14, 14, curves in the upright beams, and in the concavity of which cushions are fastened, in order to break the force of the arms, which strike against them with great force when the dart is discharged; 16, the arbor of the machine, in which a straight groove or canal is formed to receive the darts, in order to their being shot by the ballista; 17, the nut of the trigger, 18, the roll or windlass, about which the cord is wound; 19, a hook, by which the cord is drawn towards the centre, and the ballista cocked; 20, a stage or table on which the arbor is in part sustained.

BALLISTA, in Practical Geometry, the same as the geometrical cross, called also Jacob's Staff. See **CROSS-STAFF**.

BALLISTIC PENDULUM, an ingenious machine invented by Benjamin Robins, for ascertaining the velocity of military projectiles, and consequently the force of fired gunpowder. It consists of a large block of wood, annexed to the end of a strong iron stem, having a cross steel axis at the other end, placed horizontally, about which the whole vibrates together like the pendulum of a clock. This machine being at rest, a piece of ordnance is pointed straight towards the wooden block, or ball of this pendulum, and then discharged: the consequence is this; the ball discharged from the gun strikes and enters the block, and causes the pendulum to vibrate more or less according to the velocity of the projectile, or the force of the blow; and by observing the extent of the vibration, the force of that blow becomes known, or the greatest velocity with which the block is moved out of its place, and consequently the velocity of the projectile itself which struck the blow and urged the pendulum.

A more minute and particular description may be seen in my Tracts, vols. 2 & 3, where are given the various rules for using it, and for computing the velocities, with a multitude of accurate experiments performed with cannon balls, by means of which the most useful and important conclusions have been deduced in military projectiles and the nature of physics. In those Tracts are detailed at great length many experiments of the same kind, by discharging cannon balls at various distances from the block; from which have resulted the discovery of a complete series of the resistances of the air to balls passing through it with all degrees of velocity, from 0 up to 2000 feet in a second of time.

Other writers on this subject are Euler, Antoni, Le Roy, Darcy, &c. &c. See also Robins's Mathematical Tracts.

BALLISTICS, is used by some for projectiles, or the art of throwing heavy bodies. Mersenne has published a treatise on the projection of bodies, under this title.

BALLOON, or **BALLON**, in a general sense signifies any spherical hollow body. Thus, with chemists, it denotes a round short-necked vessel, used to receive what is distilled by means of fire: in architecture, a ball or globe on the top of a pillar, &c; and among engineers, a kind of bomb made of pasteboard, and played off in fireworks, in imitation of a real iron bomb-shell.

AIR-BALLOON. See **AEROSTATION**.

BALLUSTER, a small kind of column or pillar, used for ballustrades.

BALLUSTRADE, a series or row of ballusters, joined by a rail; serving for a rest to the arms, or as a fence or inclosure to balconies, altars, staircases, &c.

BAND, in Architecture, denotes any flat low member, or moulding, that is broad, but not very deep. The word *lace* sometimes means the same thing.

BANQUET, or **BANQUETTE**, in Fortification, a little foot-bank, or elevation of earth, forming a path along the inside of a parapet, for the soldiers to stand upon to discover the counterscarp, or to fire on the enemy in the moat, or in the covert way. It is commonly about 3 feet wide, and a foot and a half high.

BARITONO, in Music, a voice of low pitch between a tenor and bass.

BARLOWE (WILLIAM), an eminent mathematician and divine, of the 16th century. He was born in Pembroke-shire, his father (William Barlowe) being then bishop of St. David's. In 1560 he was entered commoner of Balliol college, Oxford; and in 1564, having taken a degree in arts, he left the university, and went to sea; but in what capacity is uncertain: however he thence acquired considerable knowledge in the art of navigation, as his writings afterwards shewed. About the year 1573, he entered into orders, and became prebendary of Winchester, and rector of Easton, near that city. In 1588 he was made prebendary of Litchfield, which he exchanged for the office of treasurer of that church. He afterwards was appointed chaplain to prince Henry, eldest son of king James the First; and, in 1614, archdeacon of Salisbury. Barlowe was especially remarkable for having been the first writer on the nature and properties of the loadstone, 20 years before Gilbert published his book on that subject. He was the first who made the inclinatory instrument transparent, and to be used with a glass on both sides. It was Barlowe also who suspended it in a compass-box, where, with 2 ounces weight, it was made fit for use at sea. He also found out the difference between iron and steel, and their tempers for magnetical uses. He likewise discovered the proper way of touching magnetical needles; and of piecing and cementing of loadstones; and also why a loadstone, being double-capped, must take up so great a weight.

Barlowe died in the year 1625.—His works are as follow:

1. **The Navigator's Supply**, containing many things of principal importance belonging to Navigation, and use of diverse Instruments framed chiefly for that purpose. Lond. 1597, 4to; dedicated to Robert earl of Essex.

2. **Magnetical Advertisement, or Diverse pertinent Observations and improved Experiments concerning the nature and properties of the Loadstone**. Lond. 1616, 4to.

3. **A Brief Discovery of the idle Animadversions of Mark Ridley, M. D. upon a treatise entitled Magnetical Advertisements**. Lond. 1618, 4to.

In the first of these pieces, Barlowe gave a demonstration of Wright's or Mercator's division of the meridian

line, as communicated by a friend; observing that "This manner of card has been publickly extant in print these thirtie yeares at least [he should have said 28 only], but a clode (as it were) and thicke miste of ignorance doth keepe it hitherto concealed: And so much the more, because some who were reckoned for men of good knowledge, have by glauncing speeches (but never by any one reason of moment) gone about what they could to disgrace it."

This work of Barlowe's contains descriptions of several instruments for the use of Navigation, the principal of which is an Azimuth Compass, with two upright sights; and as the author was very curious in making experiments on the loadstone, he treats well and fully upon the Sea-Compas. He also treated still farther on the same instrument in his second work, the Magnetical Advertisement.

BAROMETER, an instrument for measuring the weight or pressure of the atmosphere; and by that means the variations in the state of the air, foretelling the changes in the weather, and measuring heights or depths, &c.

This instrument is founded on what is called the Torricellian experiment, related below, and commonly consists of a cylindrical glass tube, open at one end; which being first filled with quicksilver, and then inverted with the open end downwards into a bason of the same, the mercury descends in the tube till it remains at about the height of 29 or 30 inches, according to the weight or pressure of the atmosphere at the time, which is just equal to the weight of that column of the quicksilver. Hence it follows that, if by any means the pressure of the air be altered, it will be indicated by the rising or falling of the mercury in the tube; or if the barometer be carried to a higher station, the quicksilver will descend in the cylinder, but when carried to a lower place, it will rise higher in the tube, according to the difference of elevation between the two places.

History of the Barometer.—About the beginning of the 17th century, when the doctrine of a plenum was in vogue, it was a common opinion among philosophers, that the ascent of water in pumps was owing to what they called nature's abhorrence of a vacuum; and that in consequence fluids might be raised by suction to any height whatever. But an accident having discovered, that water could not be raised in a pump unless the sucker reached to within 33 feet of the water in the well, it was conjectured by Galileo, who flourished about that time, that there might be some other cause of the ascent of water in pumps, or at least that the effect of this abhorrence was limited to the finite height of 33 feet. Being unable to satisfy himself on this head, he recommended the consideration of the difficulty to Torricelli, who had been his disciple. After some time Torricelli fell upon the suspicion that the pressure of the atmosphere was the cause of the ascent of water in pumps; that a column of water 33 feet high was a just counterpoise to a column of air, of the same base, and which extended up to the top of the atmosphere; and that this was the true reason why the water did not follow the sucker any farther. And this conjecture was soon after confirmed by various experiments. Torricelli considered, that if a column of water 33 feet high were a counterpoise to a whole column of the atmosphere, then a column of mercury of about 2 feet and a half high would also be a counterpoise to it, since quicksilver is nearly 14 times heavier than water, and so the 14th part of the height, or 2 feet and a half, very nearly, would be as heavy as the column of water. This reasoning was soon verified; for having filled a glass tube with quicksilver, and inverted it

into a bason of the same, the mercury presently descended till its height, above that in the bason, was about two feet and a half, just as he had estimated. And this is what has, from him, been called the Torricellian experiment.

The new opinion, with this confirmation of it, was readily acquiesced in by most of the philosophers, who repeated the experiment in various ways. Others however still adhered to the old doctrine, and raised several pretended objections against the new one; such as that there was a film or imperceptible rope of mercury, extended through the upper part of the tube, which retained the column of mercury, and kept it from falling into that in the bason. This and other objections were however soon overcome by additional confirmations of the true doctrine, particularly by varying the elevation of the place. It was hinted by Descartes and Pascal, that if the mercury be sustained in the tube by the pressure of the atmosphere, by carrying it to a higher situation, it would descend lower in the tube, having a shorter column of the atmosphere to sustain it, and vice versa. In consequence of which, Pascal engaged his brother-in-law, M. Perier, to try that experiment for him, being more conveniently situated for that purpose than he was at Paris. This he accordingly executed, by observing the height of the quicksilver in the tube, first at the bottom of the Puy de Dome, a mountain in Auvergne, and then at several stations, or different altitudes, in ascending, by which it was found that the mercury fell lower and lower all the way to the top of the mountain; by this means confirming the truth of the doctrine relating to the universal pressure of the atmosphere, and the consequent suspension of the mercury in the tube of the barometer. Thus, by the united endeavours of Torricelli, Descartes, Pascal, Mersenne, Huygens, and others, the cause of the suspension of the quicksilver in the tube of the barometer became pretty generally established.

It was some time however after this general consent, before it was known that the pressure of the air was various at different times, in the same place. This could not however remain long unknown, as the frequent measuring of the column of mercury, must soon show its variations in altitude; and experience and observation would presently show that those variations in the mercurial column, were always succeeded by certain changes in the weather, as rain, wind, frosts, &c. Hence this instrument soon came into use as the means of foretelling the changes of the weather; and on this account it obtained the name of the weather-glass, as it did that of barometer from its being the measure of the weight or pressure of the air. We may now proceed to take a view of its various forms and uses.

The Common Barometer. This is represented at fig. 1, plate iv, in the same form as it was invented by Torricelli. AB is a glass tube, of $\frac{1}{4}$, or $\frac{3}{4}$, or $\frac{1}{2}$ inch wide, the more the better, and about 34 inches long, being hermetically sealed at the top A, and the open end B immersed in a bason of quicksilver cd, which is also the better the wider it is. To fill this, or any other barometer; take a clean new glass tube, of the dimensions above named, and pour into it well purified quicksilver, with a small funnel, either of glass or paper, in a fine continued stream, till it wants about half an inch or an inch of being full; then stopping it close with the finger, invert it slowly, and the air in the empty part will ascend gradually to the other end, collecting in its ascent such other small air-bubbles as unavoidably get into the tube among the mercury, when

filling it with the funnel : and thus continue to invert it several times, turning the two ends alternately upwards, till all the air-bubbles are collected, and brought up to the open end of the tube, or till the part filled shall appear, without speck, like a fine polished steel rod." This done, pour in more quicksilver, to fill the empty part entirely, and so exclude all air from the tube: then, stopping the orifice again with the finger, invert the tube, and immerse the finger and end, thus stopped, into a basin of like purified quicksilver; in this position withdraw the finger, so shall the mercury descend in the tube to some place, as ϵ , between 28 and 31 inches above that in the basin at τ , these being the limits between which it always stands in this country on the common surface of the earth. Then measure, from the surface of the quicksilver in the basin at τ , 28 inches to σ , and 31 inches to η , dividing the space between them into inches and tenths, which are marked on a scale placed against the side of the tube; and the tenths are subdivided into hundredth parts of an inch by a sliding index carrying a vernier or nonius. (See art. Vernier.) These 3 inches, between 28 and 31, so divided, will answer for all the ordinary purposes of a stationary or chamber barometer; but for experiments on altitudes and depths, it is proper to have the divisions carried on somewhat higher, and a great deal lower down. In the proper filling and otherwise fitting up of the barometer, several circumstances are to be carefully noted; as, that the bore of the tube be pretty wide, to allow the freer motion of the quicksilver, without being impeded by an adhesion to the sides; that the basin below it be also tolerably large, at least 10 times larger in diameter than that of the tube, in order that the surface of the mercury at τ may not sensibly rise or fall with that in the tube; for the numbers marked in the scale annexed to the tube, denote their distance from a certain fixed point, and therefore cannot truly indicate the height of the column above the mercury in the vessel, unless its surface coincides with this point, and be immovable; also, that the bottom of the tube be cut off rather obliquely, that when it rests on the bottom of the basin there may be a free passage for the quicksilver; and that, to have the quicksilver very pure, it is best to boil it in the tube, in order to expel the air from it, which may be done by the following simple process. Having procured a tube of $2\frac{1}{2}$ lines or 3 lines in bore, and about half a line in thickness, fill it with mercury within two inches of the top, and hold it with the sealed end lowest, in an inclined position, over a chafing-dish of burning charcoal, presenting first the sealed end to the fire, and moving it obliquely over the chafing-dish. As the mercury is heated, the air-bubbles will assume an appearance like so many studs on the inner surface of the tube, and gradually rushing into one another, ascend towards the higher parts of the tube, which are not heated; here they are condensed and almost disappear, and after repeated emigrations they acquire a bulk by their union, which enables them at length to escape. When the mercury boils, its parts strike against each other, and against the sides of the tube, with such violence, that a person unaccustomed to this operation is ready to apprehend their force to be sufficient to break the tube. The mercury is thus freed from all heterogeneous particles contained in it, together with their surrounding atmospheres, and the air which lines the inside of the tube, which cannot be expelled in any other way, is discharged; when this last-mentioned stratum of air is thus expelled,

the tube may be afterwards emptied, and filled even with cold mercury, and will be found nearly as free from the air as before: the mercury in the tube thus prepared, will rise higher than in those of the common sort, and the barometers will more nearly correspond with each other, whereas there will be a difference of 6 or 8 lines in the ascent of the mercury in the common barometers. When this operation is completed, the mercury generally remains suspended at the top, and will not descend to its proper level without shaking the tube to bring it down. The tubes, which should not be chosen less than 3 feet long, may now be filled to their proper length. This barometer is commonly fitted up in a neat mahogany case, together with a thermometer and hygrometer, as represented in plate 4, fig. 13.

As the scale of variation is but small, being included within 2 inches in the common barometer, several contrivances have been devised to enlarge the scale, or to render the motion of the quicksilver more sensible.

Descartes first suggested a method of increasing the sensibility, which was executed by Huygens. This was effected by making the barometrical tube end in a pretty large cylindrical vessel at top, into which was inserted also the lower or open end of a much finer tube than the former, which was partly filled with water, to give little obstruction by its weight to the motion of the mercury, while it moved through a considerable space of the very fine tube by a small variation of the mercury below it, and so rendered the small changes in the state of the air very sensible. But the inconvenience was this, that the air contained in the water gradually disengaged itself, and escaped through into the vacuum in the top of the small tube, till it was collected in a body there, and by its elasticity preventing the free rise of the fluids in the tubes, spoiled the instrument as a true barometer. And this, it may be observed by-the-bye, is the reason why a water barometer cannot succeed. This barometer is here represented in fig. 2, where ca is the vessel, in which are united the upper or small water tube Ac , with the lower or mercurial one Cb .

To remedy this inconvenience, Huygens thought of placing the mercury at top, and the water at bottom, which he thus contrived. ADG (fig. 3) is a bent tube hermetically sealed at A , but open at c , of about one line in diameter, and passing through the two equal cylindrical vessels bc , ef , which are about 20 inches apart, and of 15 lines diameter, their length being 10. The mercury being put into the tube, will stand between the middle of the vessels ef and bc , the remaining space to A being void both of air and mercury. Lastly, common water, tinged with a 6th part of aqua regia, to prevent its freezing, is poured into the tube re , till it rises a foot above the mercury in de . To prevent the water from evaporating, a drop of oil of sweet almonds floats on the top of it. But the column of water will be sensibly affected by heat and cold, and consequently the accuracy of the instrument will be spoiled. For which reason other contrivances have been made, as below.

The Horizontal or Rectangular Barometer, fig. 4, was invented by J. Bernoulli and Cassini; where AB is a pretty wide cylindrical part at the top of the tube, which tube is bent at right angles at c , the lower part of it cd being turned into the horizontal direction, and closed above at a , but open at the lower end d , where the mercury cannot run out, being opposed by the pressure of the atmosphere. This and the foregoing contrivance of Huygens

are founded on a theorem in hydrostatics, viz, that fluids of the same base, press according to their perpendicular altitude, not according to the quantity of their matter; so that the same pressure of the atmosphere sustains the quicksilver that fills the tube ACP , and the cistern B , as would support the mercury in the tube alone. Hence, having fixed upon the size of the scale, as suppose the extent of 12 inches, instead of the 3, in the common barometer from 28 to 31, that is 4 times as long; then the area of a section of the cylinder AB must be 4 times that of the tube, and consequently its diameter double, since the areas of circles are as the squares of their diameters: then for every natural variation of an inch in the cylinder AB , there will be a variation of 4 inches in the tube CD .—But on account of the attrition of the mercury against the sides of the glass, and the great momentum from the quick motion in CD , the quicksilver is apt to break, and the rise and fall is no longer equable; and besides, the mercury is apt to be thrown out of the orifice at D by sudden motions of the machine.

The Diagonal Barometer of Sir Samuel Moreland, fig. 5, is another method of enlarging the natural scale of 3 inches perpendicular, or CD , by extending it to any length NC in an oblique direction. This is liable in some degree to the same inconvenience, from friction and breaking, as the horizontal one: and hence it is found that the diagonal part BC cannot properly be bent from the perpendicular more than in an angle of 45°, which only increases the scale nearly in the proportion of 7 to 5.

Dr. Hooke's Wheel Barometer, fig. 6. This was invented about 1668, and is meant to render the alterations in the air more sensible. Here the barometer-tube has a large ball AB at top, and is bent up at the lower or open end, where an iron ball C floats on the top of the mercury in the tube, to which is connected another ball H by a cord, hanging freely over a pulley, turning an index K about its centre. When the mercury rises in the part CG , it raises the ball, and the other ball descends and turns the pulley with the index round a graduated circle from N towards M and P ; and the contrary way when the quicksilver and the ball sink in the bent part of the tube. Hence the scale is easily enlarged 10 or 12 fold, being increased in proportion of the axis of the pulley to the length of the index KL . But then the friction of the pulley and axis is some obstruction to the free motion of the quicksilver. Contrivances to lessen the friction &c, may also be seen in the Philos. Trans. vol. 52, art. 29, and vol. 60, art. 10.

The Steelyard Barometer, for so' that may be called which is represented by fig. 7, which enlarges the scale in the proportion of the shorter to the longer arm of the steelyard. AB is the barometer tube, closed at A and open at B , immersed in a cylindrical glass cistern CP , which is but very little wider than the tube AB is. The barometer tube is suspended to the shorter arm of an index like a steelyard, moving on the fulcrum E , and the extremity of its longest arm pointing to the divisions of a graduated arch, with which index the tube is nearly in equilibrio. When the pressure of the atmosphere is lessened, the mercury descends out of the tube into the cistern, which raises the tube and the shorter arm of the index, and consequently the extremity of the longer moves downwards, and passes over a part of the graduated arch. And on the contrary this moves upwards when the pressure of the atmosphere increases.

The Pendant Barometer, fig. 8, was invented by M. Amon-

tons, in 1695. It consists of a single conical tube AB , hung up by a thread, the larger or open end downwards, and having no vessel or cistern, because the conical figure supplies that, and the column of mercury sustained is always equal to that in the common barometer tube; which is effected thus: when the pressure of the air is less, the mercury sinks down to a lower and wider part of the tube, and consequently the altitude of its column will be less; and on the contrary, by a greater pressure of the atmosphere, the mercury is forced up to a higher and narrower part, till the length of the column CD be equal to that in the tube of the common barometer.—The inconvenience of this barometer is, that as the bore must be made very small, to prevent the mercury from falling out by an accidental shake, the friction and adhesion to the sides of the tube prevent the free motion of the mercury.

Mr. Rowning's Compound Barometers. This gentleman has several contrivances for enlarging the scale, and that in any proportion whatever. One of these is described in the Philos. Trans. No. 427, and also in his Nat. Philos. part 2; and another in the same part, which is here represented at fig. 9. ABC is a compound tube, hermetically sealed at A , and open at C ; empty from A to D , filled with mercury from thence to B , and from hence to E with water. Hence by varying the proportions of the two tubes AE and EC , the scale of variation may be changed in any degree.

The Marine Barometer. This was first invented by Dr. Hooke, to be used at sea, being contrived so as not to be affected or injured by the motion of the ship. His contrivance consisted of a double thermometer, or a couple of tubes half filled with spirit of wine; the one sealed at both ends, with a quantity of air included; the other sealed at one end only. The former of these is affected only by the warmth of the air; but the other is affected both by the external warmth and by the variable pressure of the atmosphere. Hence, considering the spirit thermometer as a standard, the excess of the rise or fall of the other above it will show the increase or decrease of the pressure of the atmosphere. This instrument is described by Dr. Halley, in the Philos. Trans. No. 269, where he says of it, "I had one of these barometers with me in my late southern voyage, and it never failed to prognosticate and give early notice of all the bad weather we had, so that I depended thereon, and made provision accordingly; and from my own experience I conclude, that a more useful contrivance hath not for this long time been offered for the benefit of navigation."—Dr. Hooke also contrived another barometer, similar to that of Mr. Rowning above described. The Rev. J. Wilson has also described a method of insuring the sensibility of the barometer ad libitum. See Nich. Journal, No. 9, new series.

Mr. Nairne, an ingenious artist in London, has lately invented a new kind of Marine Barometer; which differs from the common barometer by having the lower part of the tube, for about 2 feet in length, made very small, to check the vibrations of the mercury, which would otherwise arise from the motions of the ship. This is also assisted by being fixed in gimbals, by a part which subjects it to be the least affected by such motions.

Another sort of Marine Barometer has also been invented by M. Passemonte, an ingenious artist at Paris. This contrivance consists only in twisting the middle of the tube into a spiral of two revolutions; by which contrivance the impulses which the mercury receives from the

motions of the ship are destroyed, by being transmitted in contrary directions.

Messrs. W. and S. Jones of London, have also constructed two excellent Marine Barometers, which seem to be well adapted to the purposes intended.

The Statical Baroscope, or Barometer, of Mr. Boyle, &c. This consists of a large glass bubble, blown very thin, and then balanced by a small brass weight. Hence these two bodies being of unequal bulk, the larger will be very much affected by a change of the density of the medium, but the less not at all that is perceptible: so that, when the atmosphere becomes denser, the ball loses more of its weight, and the brass weight preponderates; and contrariwise when the air grows lighter.

Mr. Cassell's Baroscope, or Barometer. This is described in the Philos. Trans. vol. 24, and seems to be the most sensible and exact of any. It is thus described: Suppose *ABCD* (Fig. 10) a bucket of water, wherein is placed the baroscope *xzyosm*, which consists of a body *xsm*, and a tube *zyo*, which are both concave cylinders, made of tin, or rather glass, and communicating with each other. The bottom of the tube *zy* has a leaden weight to sink it, so that the top of the body may just swim even with the surface of the water by the addition of some grain weights on the top. When the instrument is forced with its mouth downwards, the water ascends into the tube to the height *yu*. To the top is added a small concave cylinder, or pipe, to keep the instrument from sinking down to the bottom: *md* is a wire: and *ms, de* are two threads oblique to the surface of the water, which perform the office of diagonals: for while the instrument sinks more or less by an alteration in the gravity of the air, there where the surface of the water cuts the thread is formed a small bubble, which ascends up the thread while the mercury of the common baroscope ascends, and vice versa.

It appears from a calculation which the author makes, that this instrument shows the alterations in the air 1200 times more accurately than the common barometer. He observes, that the bubble is seldom known to stand still even for a minute; that a small blast of wind, which cannot be heard in a chamber, will sensibly make it sink; and that a cloud passing over it always makes it descend, &c.

While some have been increasing the sensibility of the barometer by enlarging the variations, others have endeavoured to make it more convenient by reducing the length of the tube. M. Amontons, in 1688, first proposed this alteration in the structure of barometers, by joining several tubes to one another, alternately filled with mercury and with air, or some other fluid; and the number of these tubes may be increased at pleasure: but the contrivance is perhaps more ingenious than useful.

Mairan's reduced Barometer, which is only 3 inches long, serves the purpose of a manometer, in showing the dilatations of the air in the receiver of an air-pump; and instruments of this kind are now commonly applied to this use.

The Portable Barometer, is so contrived that it may be carried from one place to another without being disordered. The end of the tube is tied up in a leathern bag not quite full of mercury; which being pressed by the air, forces the mercury into the tube, and keeps it suspended at its proper height. This bag is usually inclosed in a box, through the bottom of which passes a screw, by means of which the mercury may be forced up to the top of the tube, and prevented from breaking it by dashing

against the top when the instrument is removed from one station to another. It seems Mr. Patrick first made a contrivance of this kind: but the portable barometer has received various improvements since; and the most complete of this kind has been described by M. De Luc, in his Recherches, vol. 2, pa. 5 &c, together with the apparatus belonging to it, the method of construction and use, and the advantages attending it. Improvements have also been suggested by Sir George Shuckburgh, and Col. Roy, which have been carried into execution, with farther improvements also, by Mr. Ramsden, and other ingenious artists in London.

Sir Henry Englefield has likewise much simplified the portable barometer, reducing its weight to less than a pound and a half. See Nicholson's Journal, No. 55; Philos. Mag. No. 117; or Retrospect of Discoveries, No. 13.

Fig. 11 represents this instrument, as inclosed in its mahogany case by means of three metallic rings *aaa*. This case is a hollow cone, so shaped within as to contain steadily the body of the barometer, and is divided into three branches from *b* to *c*, forming three legs or supports for the instrument when observations are making, and sustaining it at the part *d* of the case, as it appears in Fig. 12, by an improved kind of gimbals, in which its own weight renders it sufficiently steady at any time.

A thermometer is always attached to the instrument, as a necessary appendage to it, being fastened to the body at *h*, and sunk into the surface of the frame, to preserve it from injury; the degrees of this thermometer are marked on two scales, one on each side of it, viz. the scale of Fahrenheit, and that of Reaumur; the freezing point of the former being at 32, and of the latter at 0. Also on the right-hand side of these two scales there is a third, called a scale of correction, placed oppositely to that of Fahrenheit, with the word *add* and *subtract* marked, which shows the necessary correction of the observed altitude of the mercury at any given temperature of the air, indicated by the thermometer.

The Common Chamber Weatherglass, is also usually fitted up in a neat mahogany frame, and other embellishments, to make it an ornamental piece of furniture. It consists of the common tube barometer, with a thermometer by the side of it, and an hygrometer at the top, as exhibited in fig. 13.

To the foregoing may be added a new sort of *Barometer, or Weather Instrument by the Sound of a Wire*. This is mentioned by M. Lazowski in his tour through Switzerland: it is as yet but in an imperfect state, and was lately discovered there by accident. It seems that a clergyman, though near-sighted, often amused himself with firing at a mark, and contrived to stretch a wire so as to draw the mark to him to see how he had aimed. He observed that the wire sometimes sounded as if it vibrated like a musical chord; and that after such soundings, a change always ensued in the state of the atmosphere; from whence he came to predict rain or fine weather. On making farther experiments, it was found that the sounds were most distinct when extended in the plane of the meridian. And according to the weather which was to follow, it was found that the sounds were more or less soft, or more or less continued; also fine weather, it is said, was announced by the tones of counter-tenor, and rain by those of bass. It has been said that M. Volta mounted 15 chords in this way at Pavia, to bring this method to some precision, but no accounts have yet appeared of the success of his observations.

Humboldt, the celebrated traveller, contrived a portable barometer, composed of several parts, which could be easily put together, and which should correct itself at each observation, like an astronomical instrument. In this barometer the tube is distinct from the scale; and when this breaks, its place can be supplied by another, even on the top of a mountain.

The Phenomena and Observations of the Barometer.—The phenomena of the barometer are various; but authors are not yet agreed upon the causes of them; nor is the use of it, as a weather-glass, yet perfectly ascertained, though daily observations and experience lead us still nearer to precision. Mr. Boyle observes, that the phenomena of the barometer are so precarious, that it is exceedingly difficult to form any certain general rules concerning the rise and fall of the mercury. Even that rule fails which seems to hold the most generally, viz, that the mercury is low in high winds. The best rules however that have been deduced by several authors are as follow:

Dr. Halley's Rules for judging of the Weather.

1. In calm weather, when the air is inclined to rain, the mercury is commonly low.

2. In serene, good, and settled weather, the mercury is generally high.

3. Upon very great winds, though they be not accompanied with rain, the mercury sinks lowest of all, according to the point of the compass the wind blows from.

4. The greatest heights of the mercury are found upon easterly or north-easterly winds, other circumstances alike.—The above four observations made by Dr. Halley in England appear to be most universal, as they were found by Mr. Melander to lat. 39° , and by M. de Luc to lat. 46° .

5. In calm frosty weather, the mercury commonly stands high.

6. After very great storms of wind, when the mercury has been very low, it generally rises again very fast.

7. The more northerly places have greater alterations of the barometer than the more southerly, near the equator.

8. Within the tropics, and near them, there is little or no variation of the barometer, in all weathers. For instance, at St. Helena, it is little or nothing; at Jamaica but 3-10ths of an inch, and at Naples the variation seldom exceeds an inch; whereas in England it amounts to 2 inches and a half, and at Petersburgh to $3\frac{1}{2}$ nearly.

Dr. Beal, who followed the opinion of M. Pascal, observes that, ceteris paribus, the mercury is higher in cold weather than in warm; and in the morning and evening usually higher than at mid-day.—That in settled and fair weather, the mercury is higher than either a little before or after, or in the rain; and that it commonly descends lower after rain than it was before it. And he ascribes these effects to the vapours with which the air is charged in the former case, and which are dispersed by the falling rain in the latter. If it chance to rise higher after rain, it is usually followed by a settled serenity. And that there are often great changes in the air, without any perceptible alteration in the barometer.

Mr. Patrick's Rules for judging of the Weather.—These are esteemed the best of any general rules hitherto made.

1. The rising of the mercury presages, in general, fair weather; and its falling, foul weather, as rain, snow, high winds, and storms.

2. In very hot weather, the falling of the mercury indicates thunder.

VOL. I.

3. In winter, the rising forebodes frost: and in frosty weather, if the mercury fall 3 or 4 divisions, there will certainly follow a thaw. But in a continued frost, if the mercury rises, it will certainly snow.

4. When foul weather happens soon after the falling of the mercury, expect but little of it; and on the contrary, expect but little fair weather when it proves fair shortly after the mercury has risen.

5. In foul weather, when the mercury rises much and high, and so continues for 2 or 3 days before the foul weather is quite over, then expect a continuance of fair weather to follow.

6. In fair weather, when the mercury falls much and low, and thus continues for 2 or 3 days before the rain comes; then expect a great deal of wet, and probably high winds.

7. The unsettled motion of the mercury, denotes uncertain and changeable weather.

8. You are not so strictly to observe the words engraved on the plates, as the mercury's rising and falling; though in general it will agree with them. For if it stands at *much rain*, and then rises up to *changeable*, it presages fair weather; though not to continue so long as if the mercury had risen higher. And so, on the contrary, if the mercury stood at *fair*, and falls to *changeable*, it presages foul weather; though not so much of it as if it had sunk lower.

Upon these rules of Mr. Patrick, the following *remarks* are made by Mr. Rowning; who also observes, that it is not so much the absolute height of the mercury in the tube that indicates the weather, as its motion up and down: wherefore, to pass a right judgment of what weather is to be expected, we ought to know whether the mercury is actually rising or falling; to which end the following rules are of use.

1. If the surface of the mercury be convex, standing higher in the middle of the tube than at the sides, it is a sign that the mercury is then rising.

2. But if the surface be concave, or hollow in the middle, it is then sinking. And,

3. If it be plain, or rather a little convex, the mercury is stationary: for mercury being put into a glass tube, especially a small one, naturally has its surface a little convex, because the particles of mercury attract one another more forcibly than they are attracted by glass. Farther,

4. If the glass be small, shake the tube; then if the air be grown heavier, the mercury will rise about half a 10th of an inch higher than it stood before; but if it be grown lighter, it will sink as much. And, it may be added, in the wheel or circular barometer, tap the instrument gently with the finger, and the index will visibly start forwards or backwards according to the tendency of the fluid to rise or fall at that time. This proceeds from the mercury's adhering to the sides of the tube, which prevents the free motion of it till it be disengaged by the shock: and therefore when an observation is to be made with such a tube, it ought to be first shaken; for sometimes the mercury will not vary of its own accord, till the weather is present which it ought to have indicated.

To the foregoing rules may be added the following additional ones, deduced from later and more close observation of the motions of the barometer, and the consequent changes in the air in this country.

1. In winter, spring, and autumn, the sudden falling of the mercury, and that for a large space, denotes high winds and storms; but in summer it presages heavy

showers, and thunder : and it always sinks lowest of all for great winds, though not accompanied with rain ; though it falls more for wind and rain together than for either of them alone. Also, if, after rain, the wind change into any part of the north, with a clear and dry sky, and the mercury rise, it is a certain indication of fair weather.

2. After very great storms of wind, when the mercury has been low, it commonly rises again very fast. In settled fair and dry weather, except the barometer sink much, expect but little rain ; for its small sinking then, is only for a little wind, or a few drops of rain ; and the mercury soon rises again to its former station. In a wet season, suppose in hay-time and harvest, the smallest sinking of the mercury must be regarded ; for when the constitution of the air is much inclined to showers, a little sinking in the barometer then denotes more rain, as it never then stands very high. And, if in such a season it rises suddenly, very fast, and high, expect not fair weather more than a day or two, but rather that the mercury will fall again very soon, and an immediate rain follow : the slow gradual rising, and keeping on to do so for 2 or 3 days, are most to be depended on for a week's fair weather. And the unsettled state of the quicksilver always denotes uncertain and changeable weather, especially when the mercury stands any where about the word changeable on the scale.

3. The greatest heights of the mercury, in this country, are found upon easterly and north-easterly winds ; and it may often rain or snow, the wind being in these points, and the barometer sinks little or none, or it may even be in a rising state, the effect of those winds counteracting. But the mercury sinks for wind, as well as rain, in all the other points of the compass ; but rises as the wind shifts about to the north or the east, or between those two points : but if the barometer should sink with the wind in that quarter, expect it soon to change from thence ; or else, should the fall of the mercury be much, a heavy rain is then likely to ensue, as it sometimes happens.

Cause of the Phenomena of the Barometer.

To account for the foregoing phenomena of the barometer, many hypotheses have been framed, which may be reduced to two general heads, viz, *mechanical* and *chemical*. The chief writers on these causes, are Pascal, Beal, Wallis, Garcin, Garden, Lister, Halley, Garsten, Lahire, Mariotte, Le Cat, Woodward, Leibnitz, De Mairan, Hamberger, D. Bernoulli, Muschenbroek, Chambers, De Luc, Black, &c : and an account of most of their hypotheses may be seen at large in M. De Luc's *Recherches sur les Modifications de l'Atmosphère*, vol. 1, chap. 3 ; see also the Philos. Trans. and various other works on this subject. It may suffice to notice here slightly a few of the principal of them.

Dr. Lister accounts for the changes of the barometer from the alterations by heat and cold in the mercury itself ; contracting by cold, and expanding by heat. But this, it is now well known, is quite insufficient to account for the whole of the effect.

The changes in the weight or pressure of the atmosphere must therefore be regarded as the principal cause of those in the barometer. But then, the difficulty will be to assign the cause of that cause, or whence arise those alterations that take place in the atmosphere, which are sometimes so great as to alter its pressure by the 10th part of the whole quantity. It is probable that the winds, as driven about in different directions, have a great share in

them ; vapours and exhalations, rising from the earth, may also have some share ; and some perhaps the flux and reflux occasioned in the air by the moon ; as well as some chemical causes operating between the different particles of matter.

Dr. Halley thinks the winds and exhalations sufficient ; and on this principle gives a theory, the substance of which may be comprised in what follows :

1st, That the winds must alter the weight of the air in any particular country ; and this, either by bringing together a greater quantity of air, and so loading the atmosphere of any place ; which will be the case as often as two winds blow from opposite parts, at the same time, towards the same point : or by sweeping away some part of the air, and giving room for the atmosphere to expand itself ; which will happen when two winds blow opposite ways from the same point at the same time : or lastly, by cutting off the perpendicular pressure of the air ; which is the case when a single wind blows briskly any way ; it being found by experience, that a strong blast of wind, even made by art, will render the atmosphere lighter ; and hence the mercury in a tube below it, as well as in others more distant, will considerably subside. See Philos. Trans. No. 292.

2dly, That the cold nitrous particles, and even the air itself condensed in the northern regions, and driven elsewhere, must load the atmosphere, and increase its pressure.

3dly, That heavy dry exhalations from the earth must increase the weight of the atmosphere, as well as its elastic force ; as we find the specific gravity of menstruum increased by dissolved salts and metals.

4thly, That the air being rendered heavier by these and the like causes, is thence better able to support the vapours ; which being also intimately mixed with it, make the weather serene and fair. Again, the air being made lighter from the contrary causes, it becomes unable to support the vapours with which it is replete ; these therefore precipitating, are collected into clouds, the particles of which in their progress unite into drops of rain.

Hence, he infers, it is evident that the same causes which increase the weight of the air, and render it more able to support the mercury in the barometer, do likewise produce a serene sky, and a dry season ; and that the same causes which render the air lighter, and less able to support the mercury, do also generate clouds and rain.

But these principles, though well adapted to many of the particular cases of the barometer, seem however to fall short of some of the principal and most obvious ones, besides being liable to several objections.

For first, If the wind were the sole agent in effecting these alterations, we should have no sensible alterations without a sensible wind, nor any wind without some alteration of the barometer ; both which are contrary to experience.

2dly, If two winds be supposed blowing from the same place, viz, London, opposite ways, viz, N. E. and S. W. there will be two others blowing from opposite points, viz, N. W. and S. E. to the same place ; which two last will balance the first, and bring as much air towards the point as the others swept from it. This follows from the laws of fluidity.

3dly, If the wind were the sole agent, the alterations in the height of the mercury would only be relative, or topical ; there would be still the same quantity supported at several places taken collectively ; thus, what a tube at

London lost, another at Paris, or at Pisa, or at Zurich, would gain. But we find the very contrary true in fact; for, from all the observations hitherto made, the barometers in several parts of the globe rise and fall together; so that it must be some alteration in the absolute weight of the atmosphere that accounts for the rise and fall of the mercury.

Lastly, setting aside these popular phenomena, the mercury's fall before, and rise after rain, seem to be inexplicable on the ground of this hypothesis: for suppose two contrary winds sweeping the air from over London; we know that few if any of the winds reach above a mile high; all therefore that they can do, will be to cut off a certain part of the column of air over London: if the consequence of this be the fall of the mercury, yet there is no apparent reason for the rain's following it. The vapours indeed may be let lower, but it will only be till they come into an air of the same specific gravity with themselves; and then they will be suspended as before.

Leibnitz accounted for the fall of the mercury before rain on another principle, viz. That as a body specifically lighter than a fluid, while it is sustained by it, adds more weight to that fluid than when, by being reduced in bulk, it becomes specifically heavier, and descends; so the vapour, after it is reduced into the form of clouds, and descends, adds less weight to the air than it did before; and hence the mercury sinks in the tube.—But here, granting that the drops of rain formed from the vapours always increasing in size as they fall lower, were continually accelerated also in their motion, and so the air suffer a continued loss of their weight as they descend; it may however be objected, that by the descent of the mercury the rain is foretold a much longer time before it comes, than the vapour can be supposed to take up in falling: that many times, and in different places, there falls a great deal of rain, without any sinking of the mercury at all; as also that there often happens a fall of the mercury, without any rain ensuing: and that sometimes the mercury will suddenly sink, in a short space of time, half an inch or more, which answers to 7 inches of rain, or about one third of the whole quantity falling in the whole year.

M. De Loc supposes that the changes observed in the pressure of the atmosphere, are chiefly produced by the greater or less quantity of vapours floating in it: others have attributed them to the same cause, but have given a different explanation of it. His opinion is, that vapours diminish the specific gravity, and consequently the absolute weight of those columns of the atmosphere into which they are received, and which, notwithstanding this admixture, still remain of the same height with adjoining columns that consist of pure or dry air. He afterwards vindicates and more fully explains this theory, and applies it to the solution of the principal phenomena of the barometer, as depending on the varying density and weight of the atmosphere.

Dr. James Hutton, in his Theory of Rain, printed in the Transactions of the Royal Society of Edinburgh, vol. 1, gives ingenious and plausible reasons for thinking that the diminution of the weight of the atmosphere by the fall of rain, is not the cause of the descent of the mercury in the barometer tube; but that the principal, if not the only cause, arises from the commotions in the atmosphere, which are chiefly produced by sudden changes of heat and cold in the air. "The barometer," he observes, "is an instrument necessarily connected with motions in the at-

mosphere; but it is not equally affected with every motion in that fluid body. The barometer is chiefly affected by those motions by which there are produced accumulations and abstractions of this fluid, in places or regions of sufficient extent to affect the pressure of the atmosphere on the surface of the earth. But, as every commotion in the atmosphere may, under proper conditions, be a cause of rain, and as the want of commotion in the atmosphere is naturally a cause of fair weather, this instrument may be made of great importance for the purpose of meteorological observations, though not in the certain and more simple manner in which it has been, with the increase of science, so successfully applied to the measuring of heights." See RAIN.

In the Encyclopædia Britannica there is another theory of the changes in the barometer, as depending on the heat in the atmosphere, not as producing commotions there, but as altering the specific gravity of the air by the changes of heat and cold. The principles of this theory are,—1st, That vapour is formed by an intimate union between the elements of fire and water, in consequence of which the fire or heat is so totally enveloped, and its action so perfectly suspended by the aqueous particles, that it not only loses its properties of burning and of giving light, but becomes incapable of affecting the most sensible thermometer; in which case it is said by Dr. Black to be in a latent state: and 2d, That if the atmosphere be affected by any unusual degree of heat, it thence becomes incapable of supporting so long a column of mercury as before; for which reason the barometer sinks.

From these axioms it would follow, that as vapour is formed by the union of fire with water, whether by attraction or a solution of the water in the fire, the vapour cannot be condensed till this union, attraction, or solution, be at an end. Hence the beginning of the condensation of the vapour, or the first signs of approaching rain, must be the separation of the fire which is latent in the vapour. In the beginning, this may be either slow and partial, or it may be sudden and violent: in the first case, the rain will come on slowly, and fall after a considerable time; but in the other, it will accumulate very quickly, and in a great quantity. But Dr. Black has proved, that when fire quits its latent state, however long it may have lain dormant and insensible, it always reassumes its proper qualities, and affects the thermometer just the same as if it had never been absorbed. The consequence of this must be, that in proportion as the latent heat is discharged from the vapour, those parts of the atmosphere into which it is discharged must be sensibly affected by it; and in proportion to the heat communicated to those parts, they will become specifically lighter, and the mercury will sink of course.

In the Memoirs of the Literary Society of Manchester, vol. 4, is also a curious paper on this subject, viz. Meteorological Observations made on different Parts of the Western Coast of Great Britain: arranged by T. Garnett, M. D. This paper is composed of materials furnished by several observers; those of Mr. Copland, surgeon at Dumfries, are of special importance. This gentleman is of opinion that the changes of the barometer indicate approaching hot and cold weather, with much more certainty than dry and wet. "Every remarkable elevation of the barometer," he says, "where it is of any duration, is followed by very warm or dry weather, and moderate as to wind, or by all of them: but heat seems to have most influence

and connexion; and when it is deficient, the continuance of the other two will be longer and more remarkable; therefore the calculation must be in a compound ratio of the excess and deficiency of the heat, and of the dryness of the weather in comparison of the medium of the season; and with regard to the want of strong wind, it appears to be intimately connected with the last, as they show that no precipitation is going on in any of the neighbouring regions."

In his 14th and 15th remarks, he had said,

' 14th, That the barometer being lower, and continuing so longer than what can be accounted for by immediate falls, or stormy weather, indicates the approach of very cold weather for the season; and also, cold weather, though dry, is always accompanied by a low barometer, till near its termination.'

' 15th, That warm weather is always preceded and mostly accompanied by a high barometer; and the rising of the barometer in the time of broken or cold weather, is a sign of the approach of warmer weather; and also if the wind is in any of the cold points, a sudden rise of the barometer indicates the approach of a southerly wind, which in winter generally brings rain with it.'

In the two following remarks, Mr. Copland had explained certain phenomena from a principle similar to that on which Dr. Darwin has so much insisted: Botanic Garden, I. notes p. 79, &c.

' That the falling of the barometer may proceed from a decomposition of the atmosphere occurring around or near that part of the globe where we are placed, which will occasion the electricity of the atmosphere to be repelled upwards in fine lambent portions; or driven downwards or upwards in more compacted balls of fire; or lastly, to be carried along with the rain, &c, in an imperceptible manner to the surface of the earth: the precipitation of the watery parts generally very soon takes place, which diminishes the real gravity of the atmosphere, and also by the decomposition of some of the more active parts, the air loses part of that elastic and repulsive power which it so eminently possessed, and will therefore press with less force on the mercury of the barometer than before, by which means a fall ensues.

' That the cause of the currents of air, or winds, may also be this way accounted for: and in very severe storms, where great decompositions of the atmosphere take place, this is particularly evident, such as generally occur in one or more of the West-India islands at one time, a great loss of real gravity, together with a considerable diminution of the spring of the air immediately ensues; hence a current commences, first in that direction whence the air has most gravity, or is most disposed to undergo such a change; but it being soon relieved of its superior weight or spring on that side, by the decomposition going on as fast as the wind arrives on the island, it immediately veers to another point, which then rushes in mostly with an increase of force; thus it goes on till it has blown more than half way round the points of the compass during the continuation of the hurricane. For in this manner the West-India phenomena, as well as the alteration of the wind during heavy rains in this country, can only be properly accounted for.' See remark No. 4.

Mr. C.'s 4th aphorism is, 'That the heaviest rains, when of long continuance, generally begin with the wind blowing easterly, when it gradually veers round to the south; and that the rain does not then begin to cease till the wind

has got to the west, or rather a little to the northward of it, when, it may be added, it commonly blows with some violence.'

Many other observations on the barometer, the weather, &c, may be seen in various parts of the Philos. Trans. And for some curious papers on the same, and other subjects connected with the barometer, see the Gentleman's Magazine for 1789, p. 317; also Greu's Journal of Nat. Philos. printed at Leipzig 1792, for the influence of the sun and moon on the barometer. See also a very elaborate paper on this subject in vol. 2, p. 49, &c, of the Royal Irish Trans. by Mr. Kirwan.

The Barometer applied to the Measuring of Altitudes.

The secondary character of the barometer, namely, as an instrument for measuring accessible heights or depths, was first proposed by Pascal and Descartes, as has been before observed; and succeeding philosophers have been at great pains to ascertain the proportion between the fall of the barometer and the height to which it is carried; as Halley, Mariotte, Maraldi, Scheuchzer, J. Cassini, D. Bernoulli, Horrebow, Bouguer, Shuckburgh, Roy, and more especially by De Luc, who has given a critical and historical detail of most of the attempts that have at different times been made for applying the motion of the mercury in the barometer to the measurement of accessible heights. And for this purpose serves the portable barometer, before described, (fig. 11 and 12, plate 4,) which should be made with all possible accuracy. Various rules have been given by the writers on this subject, for computing the height ascended from the given fall of the mercury in the tube of the barometer, the most accurate of which was that of Dr. Halley, till it was rendered much more so by the indefatigable researches of De Luc, by introducing into it the corrections of the columns of mercury and air, on account of heat. Other corrections and modifications of the same may be seen inserted under the article ATMOSPHERE, where the most correct rule is deduced from one single experiment only.

The Rule for computing Altitudes, is this,

Viz, $10000 \times \log. \frac{m}{n}$ is the altitude in fathoms, in the temperature of 31° : and for every degree of the thermometer above that, the result must be increased by so many times its 435th part, and diminished when below it: in which theorem m denotes the length of the column of mercury in the barometer tube at the bottom, and n that at the top of the hill, or other eminence; which lengths may be expressed in any one and the same sort of measures, whether feet, or inches, or tenths, &c, and either English, or French, or of any other nation; but the result in this case is always in fathoms, of 6 English feet each.

And the Precepts, in words, for the practice of measuring altitudes by the barometer, are these following:

1st, Observe the height of the barometer at the bottom of any height or depth, proposed to be measured; together with the temperature of the mercury by means of the thermometer attached to the barometer, and also the temperature of the air in the shade by another thermometer which is detached from the barometer.

2dly, Let the same thing be done also at the top of the said height or depth, and as near the time of the former as possible. And let those altitudes of mercury be reduced to the same temperature, if it be thought necessary, by correcting either the one or the other, viz, augmenting the height of the mercury in the colder temperature, or dimi-

nishing that in the warmer, by its 9600th part for every degree of difference between the two; and the altitudes of mercury so corrected, are those which are denoted by m and m' in the algebraic formula above.

3dly. Take out the common logarithms of the two heights of mercury, so corrected, and subtract the less from the greater, cutting off from the right hand side of the remainder three places for decimals; so shall those on the left be fathoms in whole numbers, the tables of logarithms being understood to be such as have 7 places of decimals.

4thly. Correct the number last found, for the difference of the temperature of the air, as follows: viz., Take half the sum of the two temperatures of the air, shown by the detached thermometers, for the mean one; and for every degree which this differs from the standard temperature of 31° , take so many times the 435th part of the fathoms above found, and add them if the mean temperature be more than 31° , but subtract them if it be below 31° ; so shall the sum or difference be the true altitude in fathoms, or being multiplied by 6, it will give the true altitude in English feet.

Example 1. Let the state of the barometers and thermometers be as follows, to find the altitude: viz,

Thermometers.		Barometers.	
detached.	attached.		
57	57	29·68 lower	
42	43	25·28 upper	
mean 49 $\frac{1}{2}$	diff. 14		

As 9600 : 14 : : 29·68 : ·04
cor. ·04 logs.

mean 49 $\frac{1}{2}$ $m = 29\cdot64 - 4718782$
stand. 31 $m = 25\cdot28 - 4027771$
diff. 18 $\frac{1}{2}$ As 435 : 18 $\frac{1}{2}$: : 691·011 : 29·388
cor. add 29·388

the altitude } 720·399 fathoms.
sought is } or 4322·394 feet.

Example 2. To find the altitude of a hill, when the state of the barometer and thermometer, as observed at the bottom and summit of the same are as follows: viz,

Thermometers.		Barometers.	
detached.	attached.		
35	41	29·45	
31	38	26·82	
mean 33	diff. 3		

As 9600 : 3 : : 29·45 : ·01
·01 logs.

mean 33 $m = 29\cdot44 - 4689378$
stand. 31 $m = 26\cdot82 - 4284588$
diff. 2 As 435 : 2 : : 404·790 : 1·86
cor. add 1·86

the altitude } 406·65 fathoms.
sought is } or 2439·90 feet.

See this rule investigated under the article PNEUMATICS, at the end.

N. B. The mean height of the barometer in London, on an average of two observations in every day of the year, kept at the house of the Royal Society, for many years past, is 29·88; the medium temperature, or height of the thermometer, according to the same, being 58°. But the medium height at the surface of the sea, according to Sir Geo. Shuckburgh (Philos. Trans. 1777, p. 586) is 30·04 inches, the heat of the barometer being 55°, and of the air

62°. See a learned paper in vol. 1 of the Trans. of the R. Soc. of Edinburgh, "on the Causes which affect the Accuracy of Barometrical Measurements; by John Playfair, A. M. F. R. S. Edin. and Professor of Mathematics in the University of Edinburgh;" also, another by Dr. Damer, late Professor of Mathematics and Philosophy in the University of Leyden, entitled "Dissertatio Physica et Mathematica de Montium Altitudine Barometro Metienda. Accedit Refractionis Astronomicae Theoria," in 8vo, at the Hague, 1783. Also other corrections and modifications that have been given by several philosophers, as Robison, Trembley, Englefield, Prony, Laplace, &c.

We shall now conclude this subject by an account of the height of some of the most remarkable mountains, &c, on the earth, above the surface of the ocean, in feet.

BARREL, an English vessel or cask, containing 36 gallons of beer-measure, or 32 gallons of ale-measure. The barrel of beer, vinegar, or of liquor preparing for vinegar, ought to contain $3\frac{1}{4}$ gallons, according to the standard of the ale quart.

BARREL, in clock-work, is the cylinder about which the spring is wrapped.

BARRICADE, or BARRICADO, a military term for a fence, or retrenchment, hastily made with vessels, or baskets of earth, carts, trees, stakes, or the like, to preserve an army from the shot or assault of an enemy.

BARRIER, a kind of fence made at a passage, retrenchment, gate, or such like, to stop it up against an enemy.

BARROW (Isaac), a very eminent mathematician and divine of the 17th century, was born at London in Octo-

ber, 1630, being the son of Thomas Barrow, then a linen-draper of that city, but descended from an ancient family in Suffolk. He was first placed at the Charter-house school for two or three years; where his behaviour afforded but little hopes of success in the profession of a scholar, being much addicted to fighting, and promoting it among his school-fellows; but on removal to Felsted in Essex, his disposition took a different turn, and he applied himself with great assiduity to his studies, in which he made very rapid advancement. He was first admitted a pensioner of Peter-house in Cambridge; but when he came to join the university in Feb. 1645, he was entered at Trinity-college. In 1647 he was chosen a scholar of the house, and subscribed the engagement; but afterwards repenting what he had done, he went back and struck out his name from the list. At this period he began to apply himself with great diligence to the study of all parts of literature, especially natural philosophy. He afterwards turned his attention to the profession of physic, and made considerable progress in anatomy, botany, and chemistry: he next studied divinity; then chronology, astronomy, geometry, and the other branches of the mathematics; with what success, his writings afterwards most eminently shewed. In 1649 he was chosen fellow of his college.

When Dr. Duport resigned the chair of Greek professor, he recommended his pupil Mr. Barrow for his successor, who, in his probationary exercise, showed himself equal to the character that had been given of him by this gentleman; but being suspected of favouring Arminianism, he was not preferred. This disappointment, it appears, determined him to quit the college, and visit foreign countries; but such were his finances, that he was obliged to dispose of his books, to enable him to execute that design.

He left England in June 1655, and visited France, Italy, Turkey, &c. At several places, in the course of this tour, he met with much kindness and liberal assistance from the English ambassadors, &c., which enabled him to benefit the more from it, by protracting his stay, and prolonging his journey. He spent more than a year in Turkey, and returned to England by way of Venice, Germany, and Holland, in 1659. At Constantinople he read over the works of St. Chrysostom, once bishop of that see, whom he preferred to all the other fathers.

On his return home Barrow was episcopally ordained by bishop Brownrig; and in 1660, he was chosen to the Greek professorship at Cambridge. In 1662 he was elected professor of geometry in Gresham-college; in which station he not only discharged his own duty, but supplied also the absence of Dr. Pope the astronomical professor. Among his lectures, some were on the projection of the sphere and perspective, which are lost; but his Latin oration, previous to his lectures, is still extant. About this time Mr. Barrow was offered a good living; but the condition annexed, of teaching the patron's son, made him refuse it, as thinking it too like a simoniacal contract. On the 20th of May 1663 he was elected a fellow of the Royal Society, in the first choice made by the council after their charter. The same year the executors of Mr. Lucas having, according to his appointment, founded a mathematical lecture at Cambridge, they selected Mr. Barrow for the first professor; and though his two professorships were not incompatible with each other, he chose to resign that of Gresham-college, which he did May the 20th, 1664; and at the same time his Greek professorship also. In 1669 he resigned the mathematical chair to his learned

friend Mr. Isaac Newton, having determined to quit the study of mathematics altogether for that of divinity. On leaving his professorship, he had only his fellowship of Trinity-college, till his uncle gave him a small sinecure in Wales; and Dr. Seth Ward, bishop of Salisbury, conferred on him a prebendary in his church. In the year 1670 he was created doctor in divinity by mandate; and, on the promotion of Dr. Pearson, master of Trinity-college, to the see of Chester, he was appointed to succeed him by the king's patent, bearing date the 13th of Feb. 1672; on which occasion the king was pleased to say, "he had given it to the best scholar in England." In this his majesty did not speak from report, but from his own knowledge; the doctor being then his chaplain, he used often to converse with him, and, in his humorous way, would call him an "unfair preacher," because he exhausted every subject, and left no room for others to come after him. In 1675 he was chosen vice-chancellor of the university; and he omitted no endeavours for the good of that society, nor in the line of his profession as a divine, for the promotion of piety and virtue: but his useful labours were abruptly terminated by a fever on the 4th of May, 1677, in the 47th year of his age. He was interred in Westminster Abbey, where a monument, adorned with his bust, was soon after erected by the contribution of his friends.

Dr. Barrow's works are very numerous, and indeed various—mathematical, theological, poetical, &c, and such as do honour to the English nation. They are principally as follow:

1. Euclidis Elementa. Cantab. 1655, in 8vo.
2. Euclidis Data. Cantab. 1657, in 8vo.
3. Lectiones Opticæ xviii. Lond. 1669, 4to.
4. Lectiones Geometricæ xiii. Lond. 1670, 4to.
5. Archimedis Opera, Apollonii Conicorum libri iv, Theodosii Sphericorum lib. iii; nova methodo illustrata, et succincte demonstrata. Lond. 1675, in 4to.

The following were published after his decease, viz:

6. Lectio, in qua theorematum Archimedis de sphæra et cylindro per methodum indivisibilium investigata, ac breviter investigata, exhibentur. Lond. 1678, 12mo.
7. Mathematicæ Lectiones habitaæ in scholis publicis academæ Cantabrigiensis, an. 1664, 5, 6, &c. Lond. 1683.
8. All his English works, in 3 volumes. Lond. 1683, folio.—These are all theological, and were published by Dr. John Tillotson.
9. Isaaci Barrow Opuscula; viz, Determinationes, Conclaves ad Clerum, Orationes, Poemata, &c, volumen quartum. Lond. 1687, folio.

Dr. Barrow left also several curious papers on mathematical subjects, written in his own hand, which were communicated by Mr. Jones to the author of "The Lives of the Gresham Professors," a particular account of which may be seen in that book, in the Life of Barrow.

Several of his works have been translated into English, and published: as the Elements and Data of Euclid; the Geometrical Lectures; the Mathematical Lectures; and accounts of some of them were also given in several volumes of the Philos. Trans.

It is remarkable, that Dr. Barrow's method of drawing tangents to curves is exactly similar to that by the method of fluxions, the difference being only in the notation: viz, he considered the elemental triangle, formed by the distance and the difference of two indefinitely near ordinates, with the element of the curve, as similar to the triangle formed by the ordinate, the tangent, and the subtangent;

which thence he found by this proportion: As the difference of the ordinates is to their distance, so is the ordinate to the subtangent.

Dr. Barrow must ever be esteemed, in all the subjects which exercised his pen, a person of the clearest perception, the finest fancy, the soundest judgment, the profoundest thought, and the closest and most nervous reasoning. "The name of Dr. Barrow (says the learned Mr. Granger) will ever be illustrious for a strength of mind and a compass of knowledge that did honour to his country. He was unrivaled in mathematical learning, and especially in the sublime geometry; in which he has been excelled only by his successor Newton. The same genius that seemed to be born only to bring hidden truths to light, and to rise to the heights or descend to the depths of science, would sometimes amuse itself in the flowery paths of poetry, and compose verses both in Greek and Latin. He at length gave himself up entirely to divinity; and particularly to the most useful part of it, that which has a tendency to make men wiser and better."

Several good anecdotes are told of Barrow, as well of his great integrity, as of his wit, and bold intrepid spirit and strength of body. His early attachment to fighting when a boy is some indication of the latter; to which may be added the two following anecdotes: In his voyage between Leghorn and Smyrna, the ship was attacked by an Algerine pirate, which, after a stout resistance, they compelled to sheer off, Barrow keeping his post at the gun to the last. And when Dr. Pope in their conversation asked him, "Why he did not go down into the hold, and leave the defence of the ship to those to whom it did belong?" He replied, "It concerned no man more than myself: I would rather have lost my life, than to have fallen into the hands of those merciless infidels."

There is another anecdote told of him, which showed not only his intrepidity, but an uncommon goodness of disposition, in circumstances where an ordinary share of it would have been probably extinguished. Being once on a visit at a gentleman's house in the country, where a large mastiff was kept, as he was going out one morning before day (for he was a very early riser) the fierce animal that used to be chained up during the day, and let loose at night for the security of the house, perceiving a strange person in the garden at that unusual time, set upon him with great fury. The doctor caught him by the throat, grappled with him, and throwing him down, lay upon him: once he thought of killing him; but he altered his resolution, on recollecting that this would be unjust, since the dog did only his duty, and he himself was in fault for rambling out of his room before it was light. At length he called out so loud, that he was heard by some of the family, who came presently out, and released the doctor and the dog from their disagreeable situation.

BARS, in Music, are the spaces quite through any composition, separated by upright lines drawn across the five horizontal lines, each of which either contains the same number of notes of the same kind, or so many other notes as will make up a like interval of time; for all the bars, in any piece, must be of the same length, and played in the same time.

BARS, in Architecture, are long slender pieces of wood, or iron, used to keep things secure, and at their proper assigned distances.

BARTER, or TRUCK, is the exchanging of one commodity for another; and forms a rule in the commercial

part of arithmetic, by which the commodities are properly calculated and equalled, by computing first the value of the commodity which is given, and then the quantity of the other which will be adequate to the same sum.

Example. How much wine at 70*l* per pipe must be given in barter for 500 loads of timber at 2*l* 5*s* per load?

First find the value of the commodity whose quantity is given; thus,

		500 loads at 2 <i>l</i> 5 <i>s</i> per load.
		2
s	1000	.
5	125	

1125 the value of the timber: hence, to find what quantity of wine at 70*l* per pipe will amount to this sum, say, as 70*l*: 1 pipe :: 1125*l*: 16 pipes 9 gallons the quantity sought.

BARTHOLINE (ERASMUS), a mathematician and philosopher, in the latter part of the 17th century, who died in 1698, at 73 years of age. He was successively professor of mathematics and philosophy at Copenhagen; and attained the rank of counsellor of state. He published *De Cometicis*, an. 1664 et 1665, *Opusculum ex observationibus Hafniæ habitis adornatum*. *Hafniæ*, 4to. Also, *Experimenta Crystallia Islandici*, 1670, in 4to; and *De Aere Hafniensi*, 1679, in 8vo.

BASE, or BASIS, in Chemistry, is a term applied by the old chemists to designate those substances of a fixed, inert, passive nature, which combined with, and were acted on, by more volatile or active menstrua. Thus, the alkalies, earths, and metallic oxyds, which form compound salts, by uniting with acids, were called the bases of these salts. Modern chemists, though they maintain, that in every combination the nisus or force of affinity between two ingredients is mutual and equal, have yet retained the term for the sake of precision, to express either species or families of salts which differ with regard to the acid, but agree as to the alkali, earth, or metallic oxyd which they contain. Thus, salts with a base of potash, include all those species which are formed by the combination of the various acids with the particular alkali, potash. Again, salts with an alkaline base comprehend the three families of salts with bases of potash, soda, or ammonia, as distinguished from the other salts with earthy or metallic bases.

The utility, therefore, of this mode of expression is evident; for though the compound salts are usually divided into genera according to their acids, as sulphats, nitrats, muriatis, &c, yet it is often desirable, to arrange them according to their other element or base, for which the Lavoisierian nomenclature has not particularly provided.

The term base is also used on other occasions as a method of denoting species; as when we say sulphuric acid is composed of oxygen united with the base of sulphur; the vegetable acids, of oxygen and a compound base of hydrogen and carbon. Sometimes also the word base is applied in a more indefinite manner, as in the expressions, phosphat of lime is the base of animal bone, azot is the base of muscular fibre, where it means merely the characteristic or principal part.

BASE, BASIS, in Architecture, denotes the lower part of a column or pedestal. The base of columns is differently formed in different orders: Thus, the Tuscan base consists only of a single torc, besides the plinth: the Doric has an astragal more than the Tuscan: the Ionic has a large torc over two slender scutias, separated by two

astragals: the Corinthian has two tores, two scotias, and two astragals: the Composite has an astragal less than the Corinthian: the Attic base has two tores and a scotia, and is proper for either the Ionic or Composite columns.

B A S E, in Geometry, the lowest side of any figure. Any side of a figure may be considered as its base, according to the position in which it may be conceived as standing; but commonly it is understood of the lowest side: as the base of a triangle, of a cone, cylinder, &c.

B A S E L I N E, in Perspective, denotes the common section of the picture and the geometrical plane.

B A S E R I N G, of a cannon, is the great ring next behind the vent or touch-hole.

B A S E M A T E R I A L E. See ALTERNATE.

B A S E M E N T, in Architecture, a continued base, extended a considerable length, as about a house, a room, or other piece of building.

B A S I L I C, in the ancient Architecture, was a large hall, or court of judicature, where the magistrates sat to administer justice.

B A S I L I C A, or **B A S I L I C U S**, the same as *Regulus*, or *Cor Leonis*, being a fixed star of the first magnitude in the constellation of Leo.

B A S I L I S K, in the older artillery, was a large piece of ordnance so called from its resemblance to the supposed serpent of that name. It threw an iron ball of 200 pounds weight; and was in great repute in the time of Solymann emperor of the Turks, in the wars of Hungary; but it is now grown-out of use in most parts of Europe. Paulus Jovius relates the terrible slaughter made in a Spanish ship by a single ball from one of these basilisks; after passing through the beams and planks in the ship's head, it killed upwards of 30 men. And Maffeus speaks of basilisks made of brass, each of which required 100 yoke of oxen to draw them.—More modern writers also give the name basilisk to a much smaller and sizeable piece of ordnance, made of 15 feet long by the Dutch, but of only 10 by the French, and carrying a ball of 48 pounds. The largest size of cannon now used by the English, are the 32-pounders.

B A S I S, in Geometry, the same as BASE.

B A S S, in Music, that part of a concert which is the most heard, which consists of the gravest, deepest, and longest sounds: it is played on the largest pipes or strings of common instruments; or on instruments larger than ordinary for the purpose; by some it is esteemed the basis and principal part in music, and by others as scarcely necessary in some tunes.

B A S S A N T I N (JAMES), a Scotch astronomer of the 16th century, born in the reign of James the 4th of Scotland. He was a son of the Laird of Bassantin in the Merse. After finishing his education at the university of Glasgow, he travelled through Germany and Italy, and then settled in the university of Paris, where he taught mathematics with great applause. Having acquired some property in this employment, he returned to Scotland in 1562, where he died 6 years after.

From his writings it appears he was no inconsiderable astronomer, for the age in which he lived; but, according to the fashion of the times, he was greatly addicted to judicial astrology. It was doubtless to our author that Sir James Melvil alludes in his Memoirs, when he says that his brother Sir Robert, when he was using his endeavours to reconcile the two queens Elizabeth and Mary, met with one Bassantin, a man learned in the high sciences, who told

him, "that all his travels would be in vain; for," said he, "they will never meet together; and next, there will never be any thing but dissembling and secret hatred for a while, and at length captivity and utter wreck to our queen from England." He added, "that the kingdom of England at length shall fall, of right, to the crown of Scotland: but it shall cost many bloody battles; and the Spaniards shall be helpers, and take a part to themselves for their labour." A prediction in which Bassantin partly guessed right, which it is likely he was enabled to do from a judicious consideration of probable circumstances and appearances.

Bassantin's works are,

1. *Astronomia Jacobi Bassantini Scotti*, opus absolutissimum, &c; ter. edit. Latine et Gallice. Genev. 1599. fol. This is the title given it by Torneus, who translated it into Latin from the French, in which language it was first published.

2. *Paraphrase de l'Astrolabe, avec une amplification de l'usage d'Astrolabe*. Lyons 1555. Paris 1617, 8vo.

3. *Mathematica Genethliaca*.

4. *Arithmetica*.

5. *Musica secundum Platonem*.

6. *De Mathesi in Genere*.

B A S T I O N, in the modern fortification, a large mass of earth at the angles of a work, connecting the curtains to each other; and answers to the bulwark of the ancients. It is formed by two faces, two flanks, and two demigorges. The two faces form the salient angle, or angle of the bastion; the two flanks form with the faces, the *epaules* or shoulders; and the union of the other two ends of the flanks with the curtains forms the two angles of the flanks.

The first introduction of bastions into fortification, is not precisely defined. However, they were well known soon after the year 1500; for Tartalea gives a plan of Turin, which had been completely fortified for some time with four bastions, in his *Quesiti et Inventioni diverse*, published in 1546.

If the angle of the bastion be less than 60°, it will be too small to give room for guns; and besides so acute as to be easily beaten down by the enemy's guns: to which may be added, that it will either render the line of defence too long, or the flanks too short; it must therefore be more than 60°; but whether or no it should be a right angle, some intermediate angle between 60 and 90°, or even whether or no it should exceed 90°, is still disputed, though those are generally preferred which are not much less than 90°, and not exceeding 120 or 130°. Hence it follows that a triangle can never be fortified; because either some or all of the angles will be either 60°, or less than 60°.

Bastions are of various kinds; solid, void, regular, &c.

Solid BASTIONS, are those that are entirely filled up with earth to the height of the rampart, without any void space towards the centre.

Void or Hollow BASTION, has the rampart and parapet ranging only round the flanks and spaces, so that a void space is left within towards the centre, where the ground is so low that if the rampart be taken, no retrenchment can be made in the centre, but what will lie under the fire of the besieged.

Regular BASTION, is that which has its due proportion of faces, flanks, and gorges.

Deformed or Irregular BASTION, is when the irregularity of the lines and angles throws the bastion out of shape; as when it wants one of the demigorges, one side of the interior polygon being too short, &c.

Demi BASTION, or **Half Bastion**, also otherwise called an *Epaulett*, has but one face and flank.

Double BASTION, is when one bastion is raised within, and upon the plane of another bastion.

Flat BASTION, is one built in the middle of the curtain, when it is too long to be defended by the usual bastions at the extremities.

Composed BASTION, is when the two sides of the interior polygon are very unequal, which makes the gorges also unequal.

Cut BASTION, is that which has a re-entering angle at the point, and is sometimes called a **BASTION with a Tenaille**, whose point is cut off, making an angle inwards, and two points outwards. This is used when the salient angle would be too sharp, or when water or some other impediment prevents it from being carried out to its full extent.

BASTON, or **BATOON**, in Architecture, a moulding in the base of a column, called also a *Tore*, or *Torus*.

BATTARDEAU, or **COFFERDAM**, in bridge-building, is a case of piling, &c, without a bottom, fixed in the bed of the river, by which to lay the bottom dry for a space large enough to build the pier on. When it is fixed, its sides reaching above the surface of the river, the water is drawn out by pumps, &c, and it is in like manner kept dry till the pier is built up; and then the materials of the cofferdam are drawn up. See my Tracts, vol. i, p. 100.

BATTEN, a name given by workmen to a scantling or piece of wooden stuff, about an inch thick, and from 2 to 4 inches broad; of a considerable but indeterminate length.

BATTERING, the attacking a place, work, or the like, with heavy artillery.

BATTERING-RAM, a military engine used for beating down walls before the invention of gunpowder and the modern artillery. It was no other than a long heavy beam of timber, armed with an iron head, something like the head of a ram. This being pushed violently with constant successive blows against a wall, gradually shakes it with a vibratory motion, till the stones are disjointed and the wall falls down. There were several kinds of battering-rams: the first was rude and plain, which the soldiers carried in their arms by main force, and so struck the head of it against the wall. The second was slung by a rope about the middle to another beam lying across upon a couple of posts; which was the kind described by Josephus as used at the siege of Jerusalem. A third sort was covered with a shell or screen of boards, to defend the men from the stones and darts of the besieged upon the walls, and thence called *Testudo Arictaria*. And Felibien describes a fourth sort of battering-ram, which ran upon wheels; and was the most perfect and effectual of them all.

Vitruvius affirms, that the battering-ram was first invented by the Carthaginians, while they laid siege to Cadiz; yet Pliny assures us, that the ram was invented or used at

the siege of Troy; and that it was this that gave occasion to the fable of the wooden-horse. The ram so used by the Carthaginians was of the most simple construction, being the one first mentioned. Pephames, a Tyrian, afterwards contrived to suspend it with ropes; and lastly, Polydus, the Thessalian, mounted it on wheels, at the siege of Byzantium, under Philip of Macedon. It has been suspected that the walls of Jericho, mentioned in the Book of Joshua, were beaten down with this instrument; the ram's horns there mentioned, and by means of which they were overthrown, being no other than the horns of the battering-ram.

Plutarch relates, that Marc Anthony, in the Parthian war, made use of a ram 80 feet long; and Vitruvius affirms that they were sometimes 106, and even 120 feet long; which must have given an immense force to this engine. The ram required 100 soldiers to work and manage it at one time; who being exhausted, another century relieved them; by which means it was kept playing continually. See fig. 2, plate v, which represents the battering-ram suspended in its open frame; in which 3 denotes the form of the head, fastened to the enormous beam 2, by three or four bands (4) of iron, of about four feet in breadth. At the extremity of each of these bands was an iron chain (5), one end of which was fastened to a hook (6), and to the last link at the other extremity was firmly bound a cable, which ran along the whole length of the beam to the end of the ram 7, where these cables were bound together as fast as possible with small ropes. To the end of these cables was likewise fastened another, that consisted of several strong cords platted together to a certain length, and then running single (8), at each of which were placed several men, to balance and work the machine. 10 is the chain or cable by which the ram was hung to the cross beam (11), fixed on the top of the frame; and 12 is the base of the machine.

The unsuspended ram differed from this only in the manner of working it; as it moved on small wheels upon another large beam, instead of being slung by a chain or cable.

Mr. Attwood, in his Mechanics, p. 265, has compared the effects of a battering-ram to that of a 24-pounder; the metal extremity of the ram, or the head of it, he supposes to be of the same magnitude as the shot: "In order," says he, "that the ball may have the same effect in making a breach in a wall, the weight of the ram must exceed that of the ball in the proportion of about 1700², to the square of the velocity with which this engine could be made to impinge against a wall, expressed in feet; if this may be estimated at about 10 feet in a second, the proportion of the weights will be that of about 28900000 to 100, or 28900 to 1: the weight of the battering-ram must therefore be equal to 346 ton. In this case the battering-ram and the cannon-ball, moving with the velocities of 10 feet and 1700 feet respectively in a second, would have the same effect in penetrating the substance of an opposed obstacle; but it is probable that the weight of the ram never amounted to so much as is above described, and consequently the effects of the cannon-ball to cut down walls by making a breach in them, must exceed those of the ancient battering-rams: but the momentum of these, or the impetus whereby they communicated a shock to the whole building, was far greater than the utmost force of cannon-balls; for if the weight of the battering-ram were no more than 170 times greater than that of a cannon-

ball, each moving with its respective velocity; the momenta of both would be equal: but as it is certain, that the weight of these ancient machines was far more than 170 times our heaviest cannon-balls, it follows that their momentum or impetus, to shake or overturn walls, &c, was far superior to that which is exerted by modern artillery. And since the strength of fortifications will in general be proportioned to the means which can be used for their demolition, the military walls of the moderns have been constructed with less attention with regard to their solidity and massy weight, than the ancients thought a necessary defence against the power of the ram; that sort of cohesive firmness of texture which resists the penetration of bodies being now more necessary than in ancient times: but it is manifest that even now, solidity or weight in fortifications also is of material consequence, to the effectual construction of a wall or battery."

BATTERY, in the Military Art, a place raised to plant cannon upon, to play with more advantage on the enemy. It consists of an epaulement or a breast-work, of about 8 feet high, and 18 or 20 feet thick.

In all batteries, the open spaces through which the muzzles of the cannon are pointed, are called Embrasures, guns and the distances between the embrasures, Merlons. The guns are placed on a platform composed of planks &c, ascending a little from the parapet, to check the recoil, and that the gun may be the easier brought back again to the parapet: they are placed from 12 to 16 feet distant from one another, that the parapet may be strong, and the gunners have room to work.

Mortar BATTERIES differ from the others, in that the slope of the parapet is inwards, and is without embrasures, the shells being fired quite over the parapet, commonly at an angle of 45 degrees elevation.

Open BATTERY, is nothing more than a number of cannon, commonly field-pieces, ranged in a row abreast of one another, perhaps on some small natural elevation of the ground, or an artificial bank a little raised for the purpose.

Covered or Masked BATTERY, is when the cannon and gunners are covered by a bank or breast-work, commonly made of brush-wood, faggots, and earth, called a fascine battery.

Sunk or Buried BATTERY, is when its platform is sunk, or let down into the ground, so that trenches must be cut into the earth opposite the muzzles of the guns, to serve as embrasures to fire through. This is mostly used on the first making of approaches in besieging and battering a place.

Ricochet BATTERY, so called by its inventor M. Vauban, and first used at the siege of Aeth in 1697. It is a method of firing with a very small quantity of powder, and a little elevation, so as just to fire over the parapet; and then the shot will roll along the opposite rampart, dismounting the cannon, and driving or destroying the troops. In a siege, they are generally placed at about 300 feet before the first parallel, perpendicular to the faces produced which they are to enfilade. Ricochet practice is not confined to cannon alone; small mortars and howitzers may effectually be used for the same purpose. They are of singular use in action to enfilade the enemy's ranks; for when the men perceive the shells rolling about with their fuses burning, expecting them to burst every moment, the bravest among them will not have courage to wait their approach, and face the havoc of their explosion.

Cross BATTERIES, are two batteries playing athwart each other upon the same object, forming an angle there, and battering to more effect, because what one battery shakes, the other beats down.

BATTERY d'Enfilade, is one that scours or sweeps the whole length of a straight line.

BATTERY en Echappre, is one that plays obliquely.

BATTERY de Reverse, or *Murdering Battery*, is one that plays upon the enemy's back.

Camrade or Joint BATTERY, is when several guns play upon one place at the same time.

BATTERY, in Electricity, is a combination of coated surfaces of glass, commonly jars, so connected together that they may be charged at once, and discharged by a common conductor. Mr. Gralath, a German electrician, first contrived to increase the shock by charging several phials at the same time.—Dr. Franklin, having analyzed the Leyden phial, and found that it lost at one surface the electric fire received at the other, constructed a battery of eleven large panes of sash window glass, coated on both sides, and so connected that the whole might be charged together, and with the same labour as one single pane; then by bringing all the giving sides into contact with one wire, and all the receiving sides with another, he contrived to unite the force of all the plates, and by that means to discharge them at once.—Dr. Priestley describes a still more complete battery. This consists of 64 jars, each 10 inches long, and $2\frac{1}{2}$ inches in diameter, all coated within an inch and a half of the top, forming in the whole about 31 square feet of coated surface. A piece of very fine wire is also twisted about the lower end of the wire of each jar, to touch the inside coating in several places; and it is put through a pretty large piece of cork, within the jar, to prevent any part of it from touching the side, by which a spontaneous discharge might be made. Each wire is turned round so as to make a loop at the upper end; and, through these loops passes a considerably large brass rod with knobs, each rod serving for one row of the jars; and these rods are made to communicate together by a thick chain laid over them, or as many of them as may be wanted. The jars stand in a box, the bottom of which is covered with a tin plate; and a bent wire touching the plate passes through the box, and appears on the outside. To this wire is fastened any conductor designed to communicate with the outside of the battery; and the discharge is made by bringing the brass knob into contact with any of the knobs of the battery. When a very great force is required, the size or number of the jars must be increased, or two or more batteries may be used.—But the largest and most powerful battery of all, is that employed by Dr. Van Marum, to the great electrical machine, constructed for Teyler's museum at Haarlem. This grand battery consists of a great number of jars coated as above, to the amount of about 130 square feet; and the effects of it, which are truly astonishing, are related by Dr. Van Marum in his description of this machine, and of the experiments made with it, at Haarlem 1785, &c. See also Franklin's Exper. and Observ. and Priestley's History of Electricity.

BATTERY or PILE, in Galvanism, is an apparatus employed for accumulating the electricity of galvanism, which is produced by the mutual agencies of certain metallic and carbonaceous substances, and peculiar fluids. It was invented by the celebrated Volta, from whose labours the new science of galvanism has derived many advantages,

and much improvement. Mr. Henry, in his valuable Epitome of Chemistry, gives the following easy directions for the construction of this pile: " Procure at a brazier's or coppersmith's, 30, 40, or 50 pieces of zinc, or speltre, cast in sand, of the size of half-crowns or shillings, but rather thicker. A corresponding number of half-crowns or shillings will also be required, according to the sizes of the pieces of zinc that may be employed. Let an equal number of pieces of woollen cloth be cut, of a circular shape to correspond with the pieces of zinc, and steep these in a strong solution of common salt in water. Then dispose the three substances alternately, in the following order; silver, zinc, moistened cloth; silver, zinc, &c; till a sufficient number of these triplicates, not less than 20 or 30, have been thus arranged, the silver terminating the pile at top. In order to facilitate the touching of the bottom piece of silver, it may be well to put under it a slip of tinfoil, or Dutch leaf, which may project a few inches. Next let the hands be moistened with salt and water; and on touching the piece of tinfoil with one hand, the uppermost piece of silver with the other, a shock will pass through the arms, which will be strong in proportion to the number of pieces of zinc &c employed." Of late, copper has been used instead of silver, on account of its being cheaper; and solutions of muriate of ammonia (sal-ammoniac), of nitrous acid and of muriatic acid, have been substituted for the solution of common salt with increased effect. Any two metallic substances which are perfect conductors of electricity will answer the purpose, on condition that the interposed fluid is capable of oxydation at least one of them.

Various forms of this battery have been adopted by different philosophers; but none have been brought into such general use as the galvanic trough invented by Mr. Cruicshank, of Woolwich. " It consists of a box of baked wood, in which plates of copper and zinc, or of silver and zinc, soldered together at their edges, are cemented in such a manner as to leave a number of water-tight cells corresponding to the number of the series." The common voltaic pile, on account of the loss of moisture, generally loses its electrical action in a few days, and this cannot be renewed without the trouble of reconstruction; but by Mr. Cruicshank's contrivance, which becomes active on merely filling the cells with the proper saline fluids, and freeing it when necessary from oxyd by muriatic acid, greater permanency is secured, much trouble is prevented, and much time saved.

A very powerful galvanic pile is that of M. Pepys, junior; for a description of which the reader may consult the Phil. Mag. No. 57. See also **GALVANISM**.

BATTLEMENTS, in Architecture, are notches or indentures in the top of a wall or other building, like embrasures, to look through.

BAY, in Geography, denotes a small gulf, or an arm of the sea stretching up into the land; being larger in the middle within, than at its entrance, called the mouth of the bay.

BAYER (JOHN), a German lawyer and astronomer, flourished the latter part of the 16th and beginning of the 17th century, but in what particular year or place he was born, is not known; his name however will be ever memorable in the annals of astronomy, on account of that great and excellent work which he first published in the year 1603, under the title of *Uranometria*, being a complete celestial atlas, or large folio charts of all the con-

stellations, with a nomenclature collected from the different tables of astronomy, ancient and modern, together with the useful invention of denoting the stars in every constellation by the letters of the Greek alphabet, in their order, and according to the order of their magnitude in each constellation. By means of these marks, the stars of the heavens may, with as great facility, be distinguished and referred to, as the several places of the earth are by means of geographical tables; and as a proof of the usefulness of this method, our celestial globes and atlases have ever since retained it; and hence its general use through all the literary world. Astronomers, in speaking of any star in the constellation, denote it by saying it is marked by Bayer, α , or β , or γ , &c.

BAYER lived many years after the first publication of this work, which he greatly improved and augmented by his constant attention to the study of the stars. At length, in the year 1627, it was republished under a new title, viz, *Cœlum Stellatum Christianum*, or the Christian Stellated Heaven, or the Starry Heavens Christianized: for in this work, the heathen names and characters, or figures of the constellations are rejected, and others, taken from the Scriptures, inserted in their stead, to circumscribe the respective constellations. This was the project of one Julius Schiller, a civilian of the same place. But this attempt was too great an innovation, to find success, or a general reception, which might occasion great confusion. And, we even find in the latter editions of this work, that the ancient figures and names were restored again; at least so I find them in two editions, of the years 1654, and 1661, which are now before me.

BAYLY (W.M.), a respectable astronomer and mathematician, was born at Bishop-Carions in Wiltshire, 1737, where the early part of his youth was employed in the line of his father, on a small farm in that parish; till accident threw in his way books and assistance, by which means he became qualified for an usher in a school. He afterwards passed a few years as assistant with Dr. Maskelyne, the astronomer royal at Greenwich; by whose recommendation Mr. B. in 1769, was sent out by the Royal Society to the North Cape, to observe the transit of Venus of that year; of which his account was published in the *Philos. Trans.* In 1772 Mr. B. as one of the astronomers, sailed with Capt. Cook, on his second voyage of discovery in the southern hemisphere; and again, in 1776, in the third and last voyage, which unfortunately terminated the useful life of that brave and excellent commander. On the decease of Mr. Witchell, the first master in the Royal Naval Academy at Portsmouth, in 1785, Mr. B. was appointed his successor, which situation he held, with much credit to himself, and benefit to the institution, until the new establishment of the Royal Naval College, in 1807; when Mr. B. was allowed to retire on a handsome pension, which he enjoyed till the time of his death, which happened at Portsea the latter part of 1810, at 73 years of age.

BEAD, in Architecture, is a round moulding, carved in short embossments, like beads in necklaces; and sometimes an astragal is thus carved. There is also a sort of plain bead often set on the edge of each fascia of an architrave; as also sometimes on the lining board of a door-case, the upper edge of skirting boards, &c.

BEAD, in Assaying, the small ball or mass of pure metal separated from the *scoria*, and seen distinct and pure in the middle of the coppel while in the fire.

BEAM, in Architecture, the largest piece of wood in a building; being laid across the walls, and serving to support the principal rafters of the roof. Several ingenious authors have considered the force or strength of beams, as supporting their own weight and any other additional weight; particularly Varignon, and Parent in the *Mémoire Acad. R. Scien. an. 1708*, and Mr. Emerson, on the Strength and Stress of Timber, in his Mechanics. Mr. Parent makes the proportion of the depth to the breadth of a rectangular beam to be as 7 to 5 when it is strongest.

The proportions of beams near London, are fixed by statute, as follows: a beam 15 feet long must be, at least, 7 inches on one side its square or end, and 5 on the other; if 16 feet long, the ends must be 8 inches by 6; if 17 feet long, 10 inches by 6: in country places they are usually made stronger. Sir H. Wotton advises these to be of the strongest and most durable timber. Some of the best authors have examined the force or strength of beams, and brought their resistance to a precise calculation; and the chief results of their investigations are the following:

1. The strengths of two beams, of the same wood, and of different dimensions, are to each other, as the products of their sections multiplied by the distances or heights of their centres of gravity from the base, or underside, and divided by the lengths.

2. When the lengths are equal, the strengths are as the sections multiplied by the distances of the centres of gravity above the base.

3. When the sections are equal, the strengths are as the heights of their centres of gravity divided by their lengths.

4. When the heights of the centres of gravity are equal, the strengths are as their sections divided by their lengths.

5. A rectangular beam with its narrower face upwards, is stronger than with its broader face, in proportion as the broader face is to the narrower.

6. A rectangular beam will bear a greater weight when it is fixed so, that its diagonal is in a vertical position, than when it is placed flat on one of its sides.

7. The strength of a cylindric beam, is to that of the circumscribed square one, as their sections, or as the area of a circle is to its circumscribed square, that is, as 7854 to 1, or as 11 to 14.

8. The strongest rectangular beam which can be cut out of a cylindrical tree, is that whose breadth is to its depth, as 1 to $\sqrt{2}$, or very nearly as 5 to 7.

9. The strength of a triangular beam when laid flat on its base, is double the strength of it when laid the reverse way, or with the base uppermost.

10. The stress upon a beam, to break it, by a weight laid upon the middle, is to the stress when laid nearer one end than the other, as the square of half the length, is to the product of the distances of the weight from each end. Therefore a beam will sustain the least weight in the middle, but gradually more and more towards one end.

11. When a beam is laid in an oblique position, its strength is to the strength in a horizontal position, as radius is to the cosine of the inclination.

12. A beam supported near both ends on two props, will sustain twice as much when the ends beyond the props are kept from rising, as when it rests loosely on the props. See **CARPENTRY**.

13. When a bar or beam is sustaining any *very great* compression endways, it is much easier broken by any transverse strain. Several experiments have been made on this kind of strain: a piece of white marble, for in-

stance, of $\frac{1}{4}$ an inch square, and 3 inches between the props, bore 381bs; but when compressed endways with 300lbs, it broke with 14 $\frac{1}{2}$. The difference is much more remarkable in timber and soft bodies, but it is considerable in all.

14. As the strength of the same kind of wood varies very much, it is impossible ever to come to an exact knowledge of the just proportion between the strengths of different kinds. Thus much however may be said, with regard to the two kinds commonly used for beams, &c, namely oak and fir, that the former is stronger than the latter, nearly in the proportion of 9 to 8.

BEAMS of a ship, are the large, main, cross timbers, stretched from side to side, to support the decks, and keep the sides of the ship from falling together.

BEAM of a balance, is the horizontal piece of wood or iron supported on a pivot in the middle, and at the extremities of which the two scales are suspended, for weighing any thing.

BEAM-Compass, an instrument consisting of a wooden or brass square beam, having sliding sockets carrying steel or pencil points; and are used for describing large circles, the radii of which are beyond the extent of the common compasses.

BEAR, in Astronomy, a name given to two constellations, called the *greater* and the *lesser bear*, or *URSA major* and *minor*. The pole star is in the tail of the little bear, and is within less than 2 degrees of the north pole. See *URSA, major and minor*.

BEARD, of a *Comet*, the rays which it emits in the direction in which it moves; as distinguished from the tail, or the rays emitted or left behind it as it moves along, bearing always in a direction from the sun.

BEARER, in Architecture, any subsidiary or intermediate support in aid of the principal supports, as the small joists or brackets which bear a gutter or the covering board of a cornice; the piers and blockings under the joints of a ground-floor; or the joists, &c, which bear any thing independent of or unconnected with the building; as the bearers of a cistern, of a vat, of a platform.

BEARING, in Geography and Navigation, the situation of one place from another, with regard to the points of the compass; or an arch of the horizon between the meridian of a place and a line drawn through this and another place, or the angle formed by a line drawn through the two places and their meridians.—The bearings of places on the ground are usually determined by the magnetic needle.

BEATS, in a Clock or Watch, are the strokes made by the fangs or pallets of the spindle of the balance; or of the pads in a royal pendulum. For the number and use of the beats, see *Derham's Artificial Clock Maker*, pa. 14 and seq.

BEAT, in Music, is a grace marked thus ", or thus %. Its effect is just the contrary of a transient shake in rapid movements, where it can neither be prepared nor turned.

BEAUNE (FLORIMONE), counsellor or presidial of Blois, was born in 1601, and died in 1651. He illustrated with notes the most difficult passages in the geometry of Descartes, all the mysteries of which he understood. Indeed that great man had such a respect for Beaune, that in several of his letters he declares, that he relied more on his learning and approbation, than on those of all the other mathematicians then in France.—Beaune proposed a problem which gave rise to the inverse method of tangents.

BECCARIA (JAMES BARTHOLOMEW), a celebrated mathematician and philosopher of the 17th century, was born at Bononia, in 1682, and received the early part of his education among the Jesuits. Turning his attention to the study of natural philosophy, he soon became distinguished for the variety and depth of his knowledge in physics and in mathematics, of which he was made public professor, and in conjunction with Morgagni, and other celebrated characters at Bononia, assisted in forming an academy there for teaching mathematics, natural history, chemistry, anatomy, and medicine. He was a frequent correspondent with the Royal Society of London, of which he was made an honorary member. Among other communications from Beccaria, which appear in the Phil. Trans. are his "Observations on the Weather," "On the Ignis Fatuus," and "On the power some persons have enjoyed of supporting life for a great length of time without food." This was afterwards published at Padua, under the title of "De Jejunis longis Dissertatio," folio 1748. He died Jan. 1766, being 84 years of age. Among his publications are the following:

1. *Dissertatio Meteorologica Medica, in qua aeris temperies et morbi Bononiae grassantes annis 1729 et sequenti descrubuntur.*

2. *De quamplurimis phosphoris nunc primum detectis Commentarius, in 4to, 1744 at Bonon.*

3. *Scriptura Medico-legalis, 1749.*

Besides numerous other compositions, the titles of which may be seen in Gen. Biog. and Hal. Bib. Anat.

BECCARIA (GIANBATTISTA), an eminent philosopher, and a monk of Ecoles-Pies, was a native of Mendovi, in Piedmont, and became a professor of mathematics and philosophy, first at Palermo, and next at Rome. He afterwards occupied the chair of experimental philosophy at Turin, and was appointed preceptor to the princes of Sardinia. His chief works are:

1. *Dell' Elettricismo Artificiale e Naturale, in 4to, 1753, and of which an English translation was published also in 4to, 1776.*

2. *Letteure dell' Elettricismo, folio 1758.*

3. *Gradus Taurinensis, 1774, in 4to, being an account of his measurement of a degree of the meridian near Turin, which he carefully executed between the years 1760 and 1764.*

He also published Essays on the Cause of Storms and Tempests on the meridian of Turin, &c. This philosopher, no less respected for his virtues than his knowledge, died at Turin in an advanced age, May 22, 1781.

BED, of a Great Gun, a plank laid between the cheeks of the carriage, on the middle transom, for the breech of the gun to rest upon.

BED, or Stool, of a mortar, a thick and strong planking on which a mortar is placed, hollowed a little to receive the breech and trunions.

BED-MOULDING, in Architecture, a term used by workmen for those members in a cornice, which are placed below the coronet, or crown. It usually consists of these four members, an ogee, a list, a large boulting, and another list under the coronet.

BEES, in Naval Architecture, denote pieces of elm plank bolted to the outward ends of bowsprits.

BELIGHTON (HENRY), F. R. S., was a respectable mathematician and mechanist, being well skilled in machinery, and followed the profession of a civil-engineer, being indeed the most eminent one of his time. He was the

intimate friend of Dr. Desaguliers, who received from him many valuable communications in mechanics, engines, &c., some of which may be seen in several parts of the 2d vol. of the Doctor's Course of Experimental Philosophy, particularly at pp. 431, 437, 449, 461, 472, 497, 534, 539, &c. He communicated to the Royal Society also a curious letter, containing a Description of the Water-Works at London Bridge; printed in the Philos. Trans. vol. 37, p. 5; or my Abridg. vol. 7, p. 442.

It is probable that Mr. B. died in 1743 or 1744, as it appears he conducted the Ladies' Diary for the Stationers' Company, from 1714 to 1744 inclusively; discharging that trust with such satisfaction to the company, that they permitted his widow to enjoy it for many years afterwards, by employing a deputy to compile that useful annual little book. In this almanac, for the year 1721, Mr. B. inserted a curious table of calculations on the steam-engine.

BELI'DOR (BERNARD FOREST DE), an engineer in the service of France, but born in Catalonia in 1698. He was professor in the new school of artillery at la Fere, where he published his course of mathematics for the use of the artillery and engineers. He was the first who seriously considered the quantity of gunpowder proper for charges, and reduced it to 2-3ds the quantity. He was named Associate in the Academy of Sciences in 1751; and died Sept. 8, 1761, at 63 years of age.

His works that have been published, are :

1. *Sommaire d'un Cours d'Architecture militaire, civile, et hydraulique, in 12mo, 1720.*
2. *Nouveau Cours de Mathematiques, &c. in 4to, 1725.*
3. *La Science des Ingénieurs, in 4to, 1729.*
4. *Le Bombardier Francois, in 4to, 1734.*
5. *Architecture Hydraulique, 4 vols. in 4to, 1737.*
6. *Dictionnaire portatif de l'Ingénieur, in 8vo.*
7. *Traité des Fortifications, 4 vols. in 4to.*

Besides several pieces inserted in the volumes of the Memoirs of the Academy of Sciences, for the years 1737, 1750, 1753, and 1756.

BELLA'TRIX, in Astronomy, a ruddy, glittering star of the 2d magnitude, in the left shoulder of Orion. Its name is from the Latin *bellum*, as being anciently supposed to have great influence in kindling wars, and forming warriors.

BELLOWS, a machine so contrived as to expire and inspire the air by turns, by enlarging and contracting its capacity. This machine is used in chambers and kitchens, in forges, furnaces, and foundries, to blow up the fire: it serves also for organs and other pneumatic instruments, to give them a proper supply of air. All these are of various constructions according to their different purposes; but in general they are composed of two flat boards, sometimes of an oval, sometimes of a triangular figure: two or more hoops, bent according to the figure of the boards, are placed between them; a piece of leather, broad in the middle, and narrow at both ends, is nailed on the edges of the boards, which it thus unites together; as also in the hoops which separate the boards, that the leather may the easier open and fold again: a tube of iron, brass, or copper, is fastened to the undermost board, and there is a valve within that covers the hole in the underboard, to keep the air from escaping.

BELTS, *Fascie*, in Astronomy, two zones or girdles surrounding the planet Jupiter, brighter than any of the rest of his body, and terminated by parallel lines. They are observed however to be sometimes broader and some-

times narrower, and not always occupying exactly the same part of the disc. Jupiter's belts were first observed and described by Huygens, in his Syst. Saturn. Dark spots have often been observed on the belts of Jupiter; and M. Cassini observed a permanent one on the northern side of the most southern belt, by which he determined the length of Jupiter's days, or the time in which the planet revolves upon its axis, which is 9h. 56m. Some astronomers suppose that these belts are seas, which alternately cover and leave bare large tracts of the planet's surface: and that the spots are gulfs in those seas, which are sometimes dry and sometimes full. But Azout conceived that the spots are protuberances of the belts; and others again are of opinion that the transparent and moveable spots are the shadows of Jupiter's satellites.

Cassini also speaks of the belts of Saturn; being three dark, straight, parallel bands, or *fascie*, on the disc of that planet. But it does not appear that Saturn's belts adhere to his body, as those of Jupiter do; but rather that they are large dark rings surrounding the planet at a distance. Some imagine that they are clouds in the atmosphere of Saturn, though it would seem that the middlemost is the shadow of his ring.

BENDING, the reducing a body to a curved or crooked form. The bending of boards, planks, &c, is effected by means of heat, whether by boiling or otherwise, by which their fibres are so relaxed that they may be bent into any figure. Bernoulli has a discourse on the bending of springs, or elastic bodies. And Amontons gives several experiments concerning the bending of ropes. The friction of a rope bent or wound about an immovable cylinder, is sufficient, with a very small power, to sustain very great weights.

BERENICE's Hair; see COMA *Berenices*.

BERKELEY (GEORGE), the virtuous and learned bishop of Cloyne in Ireland, was born in that kingdom, at Kilcraign, the 12th of March 1685. After receiving the first part of his education at Kilkenny school, he was admitted a pensioner of Trinity College, Dublin, at 15 years old; and chosen fellow of that college in 1707.

The first public proof he gave of his literary abilities was in his *Arithmetica absque Algebra aut Euclide demonstrata*: which from the preface it appears he wrote before he was 20 years old, though he did not publish it till 1707. It is followed by a Mathematical Miscellany, containing observations and theorems inscribed to his pupil Samuel Molinoux.

In 1709 came out the Theory of Vision; which of all his works appears to do the greatest honour to his sagacity; being the first attempt that ever was made to distinguish the immediate and natural objects of sight, from the conclusions we have been accustomed from infancy to draw from them. The boundary is here traced out between the ideas of sight and touch; and it is shown, that though habit has so connected these two classes of ideas in the mind, that they are not without a strong effort to be separated from each other, yet originally they have no such connexion: insomuch, that a person born blind, and suddenly made to see, would at first be utterly unable to tell how any object that affected his sight would affect his touch; and particularly would not from sight receive any idea of distance, or external space, but would imagine all objects to be in his eye, or rather in his mind.

Next to his Theory of Vision, in the year 1710 appeared The Principles of Human Knowledge; and in 1713 Dialogues between Hylas and Philonous: the object of both

which pieces is, to prove that the commonly received notion of the existence of matter, is false; that sensible material objects, as they are called, are not external to the mind, but exist in it, and are nothing more than impressions made upon it by the immediate act of God, according to certain rules called laws of nature.

For acuteness of parts and beauty of imagination, few authors can vie with Berkeley: his writings excited universal admiration, and his company was courted even by men of opposite parties, who also concurred in recommending him. For Steele he wrote several papers in the *Guardian*, and at his house became acquainted with Pope, with whom he always lived in friendship. Swift recommended him to the celebrated earl of Peterborough, who being appointed ambassador to the king of Sicily and the Italian States, took Berkeley with him as chaplain and secretary in 1713, with whom he returned to England the year following.

His hopes of preferment expiring with the fall of queen Anne's ministry, he some time after embraced an offer made him by Ashe, bishop of Clogher, of accompanying his son in a tour through Europe. At Paris he visited the illustrious Malebranche, whom he found in his cell cooking in a small pipkin a medicine for an inflammation of the lungs, with which he was afflicted; and as they engaged in a conversation on Berkeley's system, Malebranche in the heat of disputation, raised his voice so high, and indulged the natural impetuosity of his temper to such a degree, that he brought on an increase of his disorder, which carried him off a few days after. During four years' absence from England, he not only visited those places which fell within the grand tour, but some that are less frequented, and with great industry collected materials for a natural history of those parts, but which were unfortunately lost in his passage to Naples. He arrived at London in 1721; and being much concerned for the miseries of the nation, brought on by the disastrous South-sea scheme of 1720, he published the same year An Essay towards preventing the ruin of Great Britain: reprinted in his Miscellaneous Tracts.

The path leading to the highest company being now open, Pope introduced him to Lord Burlington, by whom he was recommended to the Duke of Grafton, then appointed lord-lieutenant of Ireland, who took Berkeley over as one of his chaplains in 1721. The latter part of this year he obtained the degrees of bachelor and doctor in divinity: and the year following he had a very unexpected increase of fortune from the death of Mrs. Vanhomrigh, the celebrated Vanessa, to whom he had been introduced by Swift: this lady had intended Swift for her heir; but perceiving herself to be slighted by him, she left her fortune, of 8000*l*, between her two executors, of whom Berkeley was one. In 1724 he was promoted to the deanery of Derry, worth 1100*l* a year.

In 1725 he published A Proposal for converting the savage Americans to Christianity, by a college to be erected in the Summer Isles, otherwise called the Isles of Bermuda, which has also been reprinted in his Miscellaneous Tracts. The proposal was well received, at least by the king; and he obtained a charter for founding the college, with a parliamentary grant of 20,000*l* towards carrying it into execution: but he could never get the money, it being otherwise employed by the ministry: so that after two years' stay in America on this business, he was obliged to return, and the scheme consequently expired.

In 1732 he published *The Minute Philosopher*, in 2 volumes 8vo, against Freethinkers. In 1733 he was made bishop of Cloyne; and might have been removed in 1745, by Lord Chesterfield, to Clogher; but declined it. He resided constantly at Cloyne, where he faithfully discharged all the offices of a good bishop, yet continued his studies with unabated attention.

About this time he engaged in a controversy with the mathematicians, which excited the highest interest in the literary world; the occasion of it was this: Mr. Addison had given the bishop an account of the behaviour of their common friend, Dr. Garth, in his last illness, which was equally displeasing to both these advocates, of revealed religion. For when Addison went to see the doctor, and began to discourse with him seriously about another world, "Surely, Addison," replied he, "I have good reason not to believe those trifles, since my friend Dr. Halley, who has dealt so much in demonstration, has assured me, that the doctrines of Christianity are incomprehensible, and the religion itself an imposture." The bishop therefore took up arms against Halley, and addressed to him, as to an Infidel Mathematician, a discourse called *The Analyst*; with a view of showing that mysteries in faith were unjustly objected to by mathematicians, who he thought admitted others much greater, and even falsehoods in science, of which he endeavoured to prove that the doctrine of Fluxions furnished a clear example. This attack gave occasion to Robins's Discourse concerning the Method of Fluxions, to Maclaurin's Fluxions, and to other smaller works on the same subject; but the direct answers to the *Analyst* were made by a person under the name of Philalethes Cantabrigiensis, but commonly supposed to be Dr. Jurin, whose first piece was, *Geometry no Friend to Infidelity*, 1734. To this the bishop replied in *A Defence of Freethinking in Mathematics*; with an Appendix concerning Mr. Walton's Vindication, 1735; which drew a second answer the same year from Philalethes, under the title of *The Minute Mathematician, or The Freethinker no just Thinker*, 1735. Other writings in this controversy, besides those before mentioned, were,

1. A Vindication of Newton's Principles of Fluxions against the objections contained in the *Analyst*, by J. Walton, Dublin, 1735.

2. The Catechism of the Author of the *Minute Philosopher* fully answered, by J. Walton, Dublin, 1735.

3. Reasons for not replying to Mr. Walton's Full Answer, in a letter to P. T. P. by the author of the *Minute Philosopher*, Dublin, 1735.

4. An Introduction to the Doctrine of Fluxions, and Defence of the Mathematicians against the objections of the author of the *Analyst*, &c. Lond. 1736.

5. A new Treatise of Fluxions; with answers to the principal objections in the *Analyst*, by James Smith, A. M. Lond. 1737.

6. Mr. Robins's Discourse of Newton's Methods of Fluxions, and of Prime and Ultimate Ratios, 1735.

7. Mr. Robins's Account of the preceding Discourse, in the Repub. of Letters, for October 1735.

8. Philalethes's Considerations upon some passages contained in two letters to the author of the *Analyst* &c, in Repub. of Letters, Novemb. 1735.

9. Mr. Robins's Review of some of the principal objections that have been made to the doctrine of Fluxions &c, Repub. of Letters for Decem. 1735.

10. Philalethes's Reply to ditto, in the Repub. of Letters, Jan. 1736.

11. Mr. Robins's Dissertation, showing that the account of the doctrines of Fluxions &c, is agreeable to the real sense and meaning of their great Inventor, &c, Repub. of Letters, April 1736.

12. Philalethes's Considerations upon ditto, in Repub. of Letters, July 1736.

13. Mr. Robins's Remarks on ditto, in Repub. of Letters, Aug. 1736.

14. Mr. Robins's Remainder of ditto, in an Appendix to the Repub. of Letters, Sept. 1736.

15. Philalethes's Observations upon ditto, in an Appendix to the Repub. of Letters, Nov. 1736.

16. Mr. Robins's Advertisement in Repub. of Letters, Decemb. 1736.

17. Philalethes's Reply to ditto, in an Appendix to the Repub. of Letters for Decem. 1736.

18. Some Observations on the Appendix to the Repub. of Letters for Decem. 1736, by Dr. Pemberton, in the Works of the Learned for Feb. 1737. With some smaller pieces in the same.

In 1736 Bishop Berkeley published "*The Querist*, a discourse addressed to magistrates, occasioned by the enormous licence and irreligion of the times;" and many other things afterward of a smaller kind. In 1744 appeared his celebrated and curious book, "*Siris; a Chain of Philosophical Reflections and Inquiries concerning the virtues of Tar-water*." It received a second impression, with additions and emendations, in 1747; and was followed by *Farther Thoughts on Tar-water*, in 1752. In July the same year he removed, with his lady and family, to Oxford, partly to superintend the education of a son, but chiefly to indulge the passion for learned retirement, which had always strongly possessed him. He would have resigned his bishopric for a canonry or headship at Oxford; but it was not permitted him. Here he lived highly respected, and collected and printed the same year all his smaller pieces in 8vo. But this happiness did not long continue, being suddenly cut off by a palsy of the heart, Jan. 14, 1753, in the 69th year of his age, while listening to a sermon that his lady was reading to him.

The excellence of Berkeley's moral character is fully attested by his writings: he was certainly a very amiable as well as a very learned man; and it is thought that Pope scarcely said too much, when he ascribed

"To Berkeley every virtue under heaven."

BERME, in Fortification, a small space of ground, 4 or 5 feet wide, left without the rampart, between it and the side of the moat, to receive the earth that rolls down from the rampart, and prevent its falling into and filling up the ditch.—Sometimes, for greater security, the berme is palisaded.

BERNARD (Dr. EDWARD), a learned English astronomer, critic, and linguist, was born at Perry St. Paul, near Towcester, the 2d of May 1638, and educated at Merchant-Taylor's school, whence he was removed in 1655 to St. John's college, Oxford. Having laid in a good fund of classical learning at school, in the Greek and Latin languages, he applied himself very diligently at the university to the study of history, the Eastern languages, and mathematics under the celebrated Dr. Wallis. In 1668 he went to Leyden, to consult some Oriental manuscripts left to that university by Joseph Scaliger and Levin Warner, and espe-

cially the 5th, 6th, and 7th books of Apollonius Pergaeus's Conics, brought from the East by the celebrated Golius. These he transcribed and brought to Oxford, with a view of publishing them, but was obliged to relinquish that design for want of proper encouragement. This however was afterwards carried into effect by Dr. Halley in 1710, with the addition of the 8th book, which he supplied by his own ingenuity and industry.

On his return to Oxford, he examined and collated the most valuable manuscripts in the Bodleian library. In 1669, the celebrated Christopher Wren, Savilian professor of astronomy at Oxford, having been appointed surveyor-general of his majesty's works, and being much detained at London by this employment, obtained leave to name a deputy at Oxford. He accordingly fixed on Mr. Bernard, which engaged the latter in a more particular application to the study of astronomy. But in 1673 he was appointed to the professorship himself, which Wren was obliged to resign, as, by the statutes of the founder, Sir Henry Saville, the professors are not allowed to hold any other office either ecclesiastical or civil. About this time a scheme was set on foot at Oxford for collecting and publishing the works of the ancient mathematicians. Mr. Bernard, who had first formed the project, collected all the old books published on that subject since the invention of printing, together with all the manuscripts he could get from the Bodleian and Savilian libraries, which he arranged in order of time, and according to the matter they contained; of these he drew up a synopsis; and as a specimen he published a few sheets of Euclid, containing the Greek text, and a Latin version, with Proclus's commentary in Greek and Latin, and learned scholia and corollaries. The synopsis itself was published by Dr. Smith, under the title of *Veterum Mathematicorum Graecorum, Latinorum, et Arabum Synopsis*.

Mr. Bernard undertook also an edition of the *Parva Syntaxis Alexandrina*; in which, besides Euclid, are contained the small treatises of Theodosius, Menelaus, Aristarchus, and Hippocrates; but it never was published.

In 1676 he was sent to France, as tutor to the dukes of Grafton and Northumberland, sons to king Charles the 2d by the duchess of Cleveland, who then lived with their mother at Paris: but the simplicity of his manners not suiting the gaiety of the duchess's family, he returned about a year after to Oxford, and pursued his studies with his usual ardour and great success. In 1691, being presented to the rectory of Brightwell in Berkshire, he quitted his professorship at Oxford, in which he was succeeded by David Gregory, professor of mathematics at Edinburgh.

In the year 1696, he undertook a voyage to Holland, to attend the sale of Golius's manuscripts, as he had once before done at the sale of Heinsius's library; and soon after his return to England, he fell into a languishing consumption, which put an end to his life the 12th of January 1696, in the 58th year of his age.

Besides his works already mentioned, he was author of many other compositions. He composed tables of the longitudes, latitudes, right-ascensions, &c., of the fixed stars; and wrote Observations on the Obliquity of the Ecliptic; and other pieces inserted in the Philosophical Transactions. He wrote also,

1. A Treatise of the Ancient Weights and Measures.
2. *Chronologia Samaritanæ Synopsis*, in two tables.
3. Testimonies of the Ancients concerning the Greek Version of the Old Testament by the Seventy.

And several other learned works. Besides a great number of valuable manuscripts left at his death.

BERNARD (Dr. JAMES), professor of philosophy and mathematics, and minister of the Walloon church at Leyden, was born September the 1st 1658, at Nions in Dauphiné. Having studied at Geneva, he returned to France in 1679, and was chosen minister of Venterol, a village in Dauphiné; but some time after he was removed to the church of Vinsobres in the same province. To avoid the persecutions against the protestants in France, he went into Holland, where he was appointed one of the penitentiary ministers of Ganda. He here published several political and historical works. And in 1699 he began the *Nouvelles de la République des Lettres*, which continued till December 1710. In 1705 he was chosen minister of the Walloon church at Leyden; and about the same time, Mr. de Volder, professor of philosophy and mathematics at Leyden, having resigned, Mr. Bernard was appointed his successor; upon which occasion the university also presented him with the degrees of doctor of philosophy and master of arts. In 1716 he published a supplement to Moreri's dictionary in 2 volumes folio. The same year he resumed his *Nouvelles de la République des Lettres*; which he continued till his death, which happened the 27th of April 1718, in the 60th year of his age.

BERNOULLI (JAMES), a celebrated philosopher and mathematician, born at Basil the 27th of December 1654. Having taken his degrees in that university, he applied himself to divinity agreeably to the entreaties of his father, but against his own inclination, which led him to astronomy and mathematics. He gave very early proofs of his genius for these sciences, and soon became a geometrician, without a preceptor, and almost without books; for if one by chance fell into his hands, he was obliged to conceal it, to avoid the displeasure of his father. This situation induced him to choose for his device, Phacton driving the chariot of the sun, with these words, *Invito patre sidera verso*, "I traverse the stars against my father's will:" alluding particularly to astronomy, to which he then chiefly applied himself.

In 1676 he began his travels. When he was at Geneva, he fell upon a method to teach a young girl to write who had been blind from her infancy. At Bourdeaux he composed universal gnomonic tables; but they were never published. He returned from France to his own country in 1680. About this time there appeared a comet, the return of which he foretold; he wrote also a small treatise upon it. Soon after this he went into Holland, where he applied himself to the study of the new philosophy. Having visited Flanders and Brabant, he passed over to England; where he formed an acquaintance with the most eminent men in science, and attended their philosophical meetings. He returned to his native country again in 1682; and exhibited at Basil a course of experiments in natural philosophy and mechanics, which consisted of a variety of new discoveries. The same year he published his *Essay on a new System of Comets*; and the year following, his Dissertation on the Weight of the Air. About this time Leibnitz having published, in the *Acta Eruditorum* at Leipzig, some essays on his new *Calculus Differentialis*, but concealing the art and method of it, Bernoulli and his brother John soon discovered, from what they saw, its beauty and extent: this induced them to endeavour to unravel the secret; which they did with such success, that

Leibnitz declared that the invention belonged to them as much as to himself.

In 1687 James Bernoulli succeeded to the professorship of mathematics at Basil; a trust which he discharged with great applause; and his reputation drew many foreigners from all parts to attend his lectures. In 1699 he was admitted a foreign member of the Academy of Sciences of Paris; and in 1701 the same honour was also conferred on him by the Academy of Berlin; in both of which he published several ingenious compositions, about the years 1702,-3, and -4. He wrote likewise several pieces in the *Acta Eruditorum* of Leipsic, and in the *Journal des Scavans*. His intense application to study brought on him the gout, and by degrees a slow fever, which terminated his life the 16th of August 1705, in the 51st year of his age—Archimedes having found out the proportion of a sphere and its circumscribing cylinder, ordered them to be engraved on his monument; in imitation thereof Bernoulli appointed that a logarithmic spiral curve should be inscribed on his tomb, with these words, *Eadem mutata resurgo*; in allusion to the hopes of the resurrection, which are in some measure represented by the properties of that curve, which he had the honour to discover.

James Bernoulli had an excellent genius for invention and elegant simplicity, as well as a close application. He was eminently skilled in all the branches of the mathematics, and contributed much to the promotion of the new analysis, infinite series, &c. He carried to a great extent the theory of the quadrature of the parabola; the geometry of curve lines, of spirals, of cycloids, and epicycloids.

His works, that had been published, were collected, and printed in 2 volumes 4to, at Geneva in 1744. At the time of his death he was occupied on a great work entitled *De Arte Conjectandi*, which was published in 4to in 1713. It contains an elegant and most excellent introduction to Infinite Series, &c. This posthumous piece is omitted in the collection of his works above mentioned.

BERNOULLI (JONES), the brother of James, last mentioned, and a celebrated mathematician, was born at Basil the 7th of August 1667. His father intended him for trade; but his own inclination was at first for the belles-lettres, which however, like his brother, he forsook for that of mathematics. He laboured with his brother to discover the method used by Leibnitz in his essays on the Differential Calculus, and gave the first principles of the Integral Calculus. Our author, with Messieurs Huygens and Leibnitz, was the first who gave the solution of the problem proposed by James Bernoulli, concerning the catenary, or curve formed by a chain suspended by its two extremities.

John Bernoulli had the degree of doctor of physic at Basil, and two years afterward was named professor of mathematics in the university of Groningen. It was here that he discovered the mercurial phosphorus or luminous barometer, occasioned by friction of mercury against glass in a vacuum; and where he also resolved the problem proposed by his brother concerning Isoperimetricals.

On the death of James, the professor at Basil, our author returned to his native country, against the pressing invitations of the magistrates of Utrecht to come to that city, and of the university of Groningen, who also wished to retain him. The Academic Senate of Basil soon appointed him to succeed his brother, without assembling competitors, and contrary to the established practice: an appointment which he held during his whole life.

VOL. I.

In 1714 was published his treatise on the management of ships; and in 1730, his memoir on the elliptical figure of the planets which gained the prize of the Academy of Sciences at Paris. The same academy also divided the prize, for their question concerning the inclination of the planetary orbits, between our author and his son Daniel.

John Bernoulli was a member of most of the academies of Europe, and received as a foreign associate of that of Paris in 1699. After a long life spent in constant study and the improvement of all the branches of the mathematics, he died full of honours the 1st of January 1748, in the 81st year of his age. Of five sons which he had, three pursued the same study with himself. One died before him; the two others, Nicholas and Daniel, he lived to see become eminent and respected in mathematical science.

The writings of this great man were dispersed through the periodical memoirs of several academies, as well as in many separate treatises. And the whole of them were carefully collected and published at Lausanne and Geneva, 1742, in 4 volumes, 4to.

BERNOULLI (JOHN), son of the preceding, was born at Basil, Jan. 17, 1695, and died at Petersburgh, July 26, 1726. He was licentiate of law, professor of law at Berne; and afterwards professor of mathematics at Petersburgh, and member of the Institute of Bologna.

BERNOULLI (NICHOLAS), nephew of the two first named, was professor of mathematics at Padua, afterwards of logic, and then of law at Basil. He was member of the Academy of Sciences and Belles-Letters at Berlin, and also of the Royal Society of London, and of the Institute of Bologna; was born at Basil, Oct. 10, 1687, where he also died the 29th of Nov. in the year 1759.

BERNOULLI (DANIEL), a celebrated physician and philosopher, son of John, and nephew of James, was born at Groningen Feb. the 9th, 1700, where his father was then professor of mathematics. He was first designed for trade, but his genius led him to other pursuits. He passed some time in Italy; and at 24 years of age he declined the honour offered him of becoming president of an academy intended to have been established at Genoa. He spent several years with great credit at Petersburgh; and in 1733 returned to Basil, where his father was then professor of mathematics; and here our author successively filled the chair of physic, of natural and of speculative philosophy.

In his work *Exercitationes Mathematicæ*, 1724, he took the only title he then had, viz., "Son of John Bernoulli," and never would suffer any other to be added to it. This work was published in Italy, while he was there on his travels; and it classed him in the rank of inventors. His work entitled *Hydrodynamica*, was published in 4to at Argentoratum or Strasbourg, in 1738.

Daniel Bernoulli wrote a multitude of other pieces, which have all been published either in the Mem. of the Acad. of Sciences at Paris, or in those of other Academies. He gained and divided ten prizes from the Academy of Sciences at Paris, which were contended for by the most illustrious mathematicians in Europe. The only person who has had similar success is Euler, his countryman, disciple, rival, and friend. His first prize he gained at 24 years of age. In 1734 he divided that with his father respecting the inclination of the orbits of the planets; which hurt the family union; for the father considered the contest itself as a want of respect; and the son did not sufficiently conceal that he thought (what was really the case)

2 G

his own piece better than his father's. And besides, he declared for Newton, against whom his father had contended all his life. In 1740 our author divided the prize, "On the Tides of the Sea," with Euler and Maclaurin. The Academy at the same time rewarded a fourth piece, the chief merit of which was that of being Cartesian; but this was the last public act of adoration paid by the Academy to the authority of the author of the *Vortices*, which it had already obeyed too long. In 1748 Daniel Bernoulli succeeded his father John in the Academy of Sciences, who had succeeded his brother James; this place, since its first erection in 1699, having never been without a Bernoulli to fill it.

Our author was extremely respected at Basil; and to bow to Daniel Bernoulli, when they met him in the streets, was one of the first lessons which every father gave to his child. He was a man of great simplicity and modesty of manners. He used to tell two little adventures, which he said had given him more pleasure than all the other honours he had received. Travelling with a learned stranger, who, being pleased with his conversation, asked his name; "I am Daniel Bernoulli," answered he with great modesty; "and I," said the stranger (who thought he meant to laugh at him) "am Isaac Newton." Another time, having to dine with him the celebrated Koenig, the mathematician, who boasted, with some degree of self-complacency, of a difficult problem he had resolved with much trouble, Bernoulli went on doing the honours of his table, and when they went to drink coffee he presented Koenig with a solution of the problem more elegant than his own.

After a long, useful, and honourable life, Daniel Bernoulli died the 17th of March, 1782, in the 83d year of his age.

BÉRNOLLI (JAMES), another mathematical branch of the foregoing celebrated family. He was born at Basil in October 1739; being the son of John Bernoulli, and grandson of the first John Bernoulli, before mentioned, and the nephew of Daniel Bernoulli last noticed. Our author's elder brother John, who still lives at Berlin, is also well known in the republic of science, particularly for his astronomical labours.

The gentleman to whom this article relates, was educated, as most of his relations had been, for the profession of the law: but his genius led him very early into the study of mathematics; and at 20 years of age he read public lectures on experimental philosophy in the university of Basil, for his uncle Daniel Bernoulli, whom he hoped to have succeeded as professor. Being disappointed in this view, he resolved to leave his native place, and to seek his fortune elsewhere; hence he accepted the office of secretary to Count Breuner, the emperor's envoy to the republic of Venice; and in this city he remained till the year 1786, when, on the recommendation of his countryman, M. Fuss, he was invited to Petersburg to succeed M. Lexell in the academy there, where he continued till his death, which happened the 3d of July 1789, at not quite 30 years of age, and when he had been married only two months, to the youngest daughter of John Albert Euler, the son of the celebrated Leonard Euler.

BETELGEUSE, a fixed star of the first magnitude in the right shoulder of Orion.

BEVIS (JOHN, M. D.), an able astronomer, was born October 31, 1695, near Old Sarum in Wiltshire. He was entered at Christ-Church College, Oxford, where he applied himself diligently, not only to the study of physic,

for which he was designed, but to other sciences, particularly astronomy and optics, in which he became a considerable proficient. After taking the degree of M. D. he left the university, and devoted himself almost entirely to pursuits connected with astronomy. In 1738 he made an excellent collection of astronomical instruments for a new observatory, which he had erected at Newington Green, in Middlesex. Here he became an indefatigable observer, often observing the transits of 160 stars in one night.—About 1745 the doctor undertook the laborious task of arranging a work called *Uranographia Britannica*, or an *Exact View of the Heavens*, on 52 plates, similar to Baye's work representing the constellations, &c. The plates, which would have done great honour as well to the nation as Dr. Bevis, were engraved but never published, the doctor having consigned the management of them to a person who became bankrupt. Dr. Bevis was the real author of a great many works which have been well received by the public, but which his modesty prevented him from taking the merit of. It is to him we are indebted for the publication of Dr. Halley's Astronomical Tables, after they had been printed more than 20 years: having supplied some auxiliary tables, and the precepts for using them, he favoured the public with the whole in the year 1749. In Mr. Simpson's *Essays*, p. 10, are delivered practical rules for finding the aberration, which were drawn up and given him by Dr. Bevis, with examples of the correction applied to several stars, which he had carefully observed with proper instruments; by which he proved, first of any one, that the phenomena are as conformable in right ascension, as Dr. Bradley, who made this great discovery, found they were in declination. Several pieces by the doctor were inserted in the few numbers that were published of a work called the *Mathematical Magazine*, by Messrs. Whitchell and Moss; particularly a curious paper on the satellites of Venus, and several sheets of a new mathematical dictionary. Dr. Bevis enriched the *Philosophical Transactions* with 27 valuable papers, from vol. 40 to vol. 59 inclusive: The only pieces which appeared separately with his name, besides these papers in the *Transactions*, were two pamphlets, the one entitled *The Satellite's Sliding Rule*, for determining the immersions and emersions of Jupiter's four satellites. The other was *An Experimental Enquiry concerning the Contents, Qualities, and Medicinal Virtues, of the Two Mineral Waters lately discovered at Bagning-Wells, near London*, 1760. He was the first who appropriated the term achromatic to the curious telescopes invented by Mr. Dollond. On the death of Mr. Bliss in 1765, Dr. Bevis was a candidate with Dr. Maskelyne for the honourable and important situation of Astronomer Royal. Soon after which, he removed from Newington to the Temple, London, where he followed his occupation as a physician, and continued to make astronomical observations. Here he died, Nov. 6, 1771, at 76 years of age; his death having been occasioned by a fall he received a short time before, in going too hastily from his instrument to the clock when observing the sun's meridian altitude.

BEZOUT (STEPHEN), a celebrated French mathematician, Member of the Academies of Sciences and the Marine, and Examiner of the Guards of the Marine and of the *Elèves of Artillery*, was born at Nemours the 31st of March, 1730. In the course of his studies he met with some books of geometry, which gave him a taste for that science; and the *Eloges of Fontenelle*, which shewed him the honours that attended talents and the love of the sci-

ences. His father in vain opposed the strong attachment of young Bezout to the mathematical sciences. April 8, 1758, he was named adjoint-mechanician in the French Academy of Sciences; having before that sent them two ingenious memoirs on the integral calculus, and given other proofs of his proficiency in the sciences. In 1763 he was named to the new office of Examiner to the Marine, and appointed to compose a Course of Mathematics for their use; and in 1768, on the death of M. Camus, he succeeded as Examiner of the Artillery Élèves.

Bezout fixed his attention more particularly to the resolution of algebraic equations; and he first found out the solution of a particular class of equations of all degrees. This method, different from all former ones, was general for the cubic and biquadratic equations, and just became particular at those of the fifth degree. At this work of finding the roots of equations, our author laboured from 1762 till 1779, when he published it. He composed two courses of mathematics; the one for the Marine, the other for the Artillery. The foundation of these two works was the same; the applications only being different, according to the two different objects: these courses have every where been held in great estimation. In his office of Examiner, he discharged the duties with great attention, care, and tenderness. A trait of his justice and zeal is remarkable in the following instance: During an examination which he held at Toulon, he was told that two of the pupils could not be present, being confined by the small-pox; he himself had never had that disease, and he was greatly afraid of it; but as he knew that if he did not see these two young men, it would much impede their advancement, he ventured therefore to their bed-sides, to examine them, and was happy to find them so deserving the hazard he had made for their benefit.

M. Bezout lived thus several years, beloved of his family and friends, and respected by all, enjoying the fruits and the credit of his labours. But the trouble and fatigues of his offices, with some personal chagrins, had reduced his strength and constitution; he was attacked by a malignant fever, of which he died Sept. 27, 1783, in the 54th year of his age, regretted by his family, his friends, the young students, and by all his acquaintance in general.

The books published by him were:

1. Course of Mathematics for the use of the Marine, with a Treatise on Navigation; 6 vols, in 8vo. Paris, 1764.

2. Course of Mathematics for the Corps of Artillery; 4 vols, in 8vo, 1770.

3. General Theory of Algebraic Equations, 1779.

His papers printed in the volumes of the Memoirs of the Academy of Sciences, are:

1. On curves whose rectification depends on a given quantity, in the vol. for 1758.

2. On several classes of equations that admit of an algebraical solution, 1762.

3. First vol. of a course of mathematics, 1764.

4. On certain equations, &c. 1764.

5. General resolution of all equations, 1765.

6. Second vol. of a course of mathematics, 1765.

7. Third vol. of the same, 1766.

8. Fourth vol. of the same, 1767.

9. Integration of differentials, &c. vol. 3, Sav. Etr.

10. Experiments on cold, 1777.

BIANCHINI (FRANCIS), a very learned Italian philosopher and mathematician of the 17th century, was born

at Verona the 13th of December, 1662. He was highly esteemed by the learned, and was a member of several academies; and was even the founder of that at Verona, called the Academy of Aletoffili, or Lovers of Truth. He went to Rome in 1684; and was made librarian to Cardinal Ottoboni, who was afterwards Pope by the name of Alexander the 8th. He entered into the church, and became canon of St. Mary de la Rotondo, and afterward of St. Lawrence in Damaso.

Bianchini was author of several learned and ingenious dissertations. In 1697 he published *La Istoria universale provata con monumenti, et figurata con simboli degli antichi*. In 1701 Pope Clement the 11th named him secretary of the conferences for the reformation of the calendar; in which situation he published in 1703, *De Calendario et Cyclo Cæsaris, ac de Canone Paschali sancti Hypoliti, Maityris, Dissertations duæ*. Bianchini was employed likewise to construct the large gnomon in the church of the Chartroux at Rome, on which he published an ample dissertation entitled, *De Nummo et Gnomone Clementino*. The research concerning the parallax and the spots of Venus occupied him a long time; but his most remarkable discovery is that of the parallelism of the axis of Venus in her orbit. He was employed 8 years in preparing means for tracing a meridian line through the whole extent of Italy, but he never commenced this undertaking. He was admitted a foreign Associate in the Paris Academy of Sciences, in 1706; and had many astronomical dissertations inserted in their Memoirs, particularly in those of years 1702, 1703, 1704, 1706, 1707, 1708, 1713, and 1718. —Bianchini died the 2d of March, 1729, in the 67th year of his age.

BILLION, in Numeration, the same as a million millions; as much as to say bismillion or bimillion, or by further contraction, billion.

BILLY (JAMES DE), of Compeigne, a Jesuit, died in 1679 at Dijon, aged 77. He was a respectable mathematician, and published some good works in that science; as,

1. *Nova Geometriæ Clavis Algebra*. Paris, 1643, in 4to.

2. *Tabulæ Lodoiceæ de Doctrina Eclipsion*. Divisionæ, 1656, in 4to.

3. *De Proportione Harmonica Tractatus*. Paris, 1658, in 4to.

4. *Diophantus Geometria, ex Græco versa, in qua per rationes Euclidianas efficiuntur Problematæ, quæ ille Rationibus Algebraicis endavit*. Paris, 1660, in 4to.

5. *Opus Astronomicum*. In which he explained the hypotheses and motions of the stars, and every thing relating to the theory and practice of astronomy. Dijon, 1661, in 4to.

6. *Crisis Astronomica, de Motu Cometarum*. In which he refuted the rectilinear hypothesis, and discovered a new system of comets. Dijon, 1666, in 8vo.

7. *Diophantes Redivivus*. Lyons, 1670, in 8vo.

8. *Doctrina Analyticæ inventum novum*. Contained in the Commentaries on Diophantus, composed by M. Fermat. Toulouse, 1671, in folio.

• **BIMEDIAL Line**, is the sum of two medials. Euclid reckons two of these bimedials, in pr. 38 and 39, lib. x; the first is when the rectangle is rational, which is contained by the two medial lines whose sum makes the bimedium; and the second when that rectangle is a medial, or contained under two lines that are commensurable only in power.

BINARY Number, that which is composed of two units.

BINARY Arithmetic, that in which two figures or characters, viz. 1 and 0, only are used; the cipher multiplying every thing by two, as in the common arithmetic by 10: thus, 1 is one, 10 is 2, 11 is 3, 100 is 4, 101 is 5, 110 is 6, 111 is 7, 1000 is 8, 1001 is 9, 1010 is ten; being founded on the same principles as common arithmetic. This kind of arithmetic was invented by Leibnitz, who pretended that it is better adapted than the common arithmetic, for discovering certain properties of numbers, and for constructing tables; but he does not venture to recommend it for ordinary use, on account of the great number of places of figures requisite to express all numbers, even very small ones. Jos. Pelican, of Prague, has more largely explained the principles and practice of the binary arithmetic, in a book entitled *Arithmetica Perfectus, qui tria numerare nescit*: 1712. And De Lagni proposed a new system of logarithms, on the plan of the binary arithmetic; which he finds shorter, and more easy and natural than the common ones.

BINOCLE, or BINOCULAR TELESCOPE, is one by which an object is viewed with both eyes at the same time. It consists of two tubes, each furnished with glasses of the same power, by which means it has been said to show objects larger and more clearly than a monocular or single telescope; though this is probably only an illusion, occasioned by the stronger impression which two equal images, alike illuminated, make upon the eyes: they are however more embarrassing than useful. This telescope has been chiefly treated of by the fathers Reita and Cherubin of Orleans.—There are also microscopes of the same kind, though but little used, being subject to the same inconveniences as the telescopes.

BINOMIAL, a quantity consisting of two terms or members connected by the sign + or -, viz. plus or minus; as $a + b$, or $3a - 2c$, or $a^2 + b$, or $x^2 - 2\sqrt{c}$, &c.; denoting the sum or the difference of the two terms. When either term is negative, the binomial is sometimes called a residual, and by Euclid an apotome. The term binomial was first introduced by Lucas de Burgo. See his *Arithm. carta 120, edit. 1494.*

BINOMIAL Line, or Surd, is that in which at least one of the parts is a surd. Euclid enumerates six kinds of binomial lines or surds, in the 10th book of his Elements, which are exactly similar to the 6 residuals or apotomes there treated of also, and of which an account is given under the art. **APOTOME**, which see. Those apotomes become binomials by only changing the sign of the latter term from minus to plus, which therefore are as below.

Euclid's 6 Binomial Lines.

- 1st binomial $3 + \sqrt{5}$,
- 2d binomial $\sqrt{18} + 4$,
- 3d binomial $\sqrt{24} + \sqrt{18}$,
- 4th binomial $4 + \sqrt{3}$,
- 5th binomial $\sqrt{6} + 2$,
- 6th binomial $\sqrt{6} + \sqrt{2}$.

To extract the Square Root of a Binomial, as of $a + \sqrt{b}$, or $\sqrt{c} + \sqrt{b}$.—Various rules have been given for this purpose. The first is that of Lucas de Burgo, in his *Summa de Arithm. &c.*, which is this: When one part, as a , is rational, divide it into two parts such, that their product may be equal to $\frac{1}{4}$ of the number under the radical b ; then shall the sum of the roots of those parts be the root of the binomial sought: or their difference is the root when the quantity is residual; that is, if $c + e = a$, and $c e = \frac{1}{4} b$; then is $\sqrt{c} + \sqrt{e} = \sqrt{(a + \sqrt{b})}$ the root sought. For

example, let the binomial be $23 + \sqrt{448}$; then the parts of 23 are 16 and 7, and their product is 112, which is $\frac{1}{4}$ th of 448; therefore the sum of their roots $4 + \sqrt{7}$ is the root sought of $23 + \sqrt{448}$.

Lucas de Burgo gives also another rule for the same extractions, which is this: The given binomial being, for example, $\sqrt{c} + \sqrt{b}$, its root will be $\sqrt{[\frac{1}{2}\sqrt{c} + \frac{1}{2}\sqrt{(c-b)}] + \sqrt{[\frac{1}{2}\sqrt{c} - \frac{1}{2}\sqrt{(c-b)}]}}$.—So, in the foregoing example, $23 + \sqrt{448}$, here $\sqrt{c} = 23$, and $\sqrt{b} = \sqrt{448}$; hence $\frac{1}{2}\sqrt{c} = 11\frac{1}{2}$, and $\frac{1}{2}\sqrt{(c-b)} = \frac{1}{2}\sqrt{(23^2 - 448)} = \frac{1}{2}\sqrt{81} = 4\frac{1}{2}$; therref. $\sqrt{[\frac{1}{2}\sqrt{c} + \frac{1}{2}\sqrt{(c-b)}]} = \sqrt{(11\frac{1}{2} + 4\frac{1}{2})} = 16 = 4$, and $\sqrt{[\frac{1}{2}\sqrt{c} - \frac{1}{2}\sqrt{(c-b)}]} = \sqrt{(11\frac{1}{2} - 4\frac{1}{2})} = \sqrt{7}$; conseque. $4 + \sqrt{7}$ is the root sought, as before. Again, if the binomial be $\sqrt{18} + \sqrt{10}$; here $c = 18$, and $b = 10$; therref. $\frac{1}{2}\sqrt{c} = \frac{1}{2}\sqrt{18} = \frac{3}{2}\sqrt{2}$, and $\frac{1}{2}\sqrt{(c-b)} = \frac{1}{2}\sqrt{8} = \sqrt{2}$; hence, $\sqrt{[\frac{1}{2}\sqrt{c} + \frac{1}{2}\sqrt{(c-b)}]} = \sqrt{(\frac{3}{2}\sqrt{2} + \sqrt{2})} = \sqrt{\frac{5}{2}\sqrt{2}} = \sqrt{\frac{25}{2}}$, and $\sqrt{[\frac{1}{2}\sqrt{c} - \frac{1}{2}\sqrt{(c-b)}]} = \sqrt{(\frac{3}{2}\sqrt{2} - \sqrt{2})} = \sqrt{\frac{5}{2}}$; consequently, $\sqrt{\frac{25}{2}} + \sqrt{\frac{1}{2}} = \frac{\sqrt{5+1}}{\sqrt{2}}$ or $\frac{\sqrt{5+1}}{\sqrt{2}}$ is the root of $\sqrt{18} + \sqrt{10}$ sought. This latter rule has been used by all authors, down to the present time.

To extract the Cubic and other higher Roots of a Binomial. This is useful in resolving cubic and higher equations, and was introduced with the resolution of those equations by Tartalea and Cardan. The rules for such extractions are in great measure tentative; some of the principal ones of which are the following.

Tartalea's Rule for the Cube Root of a Binomial $p+q$. This rule is given in his 9th book of *Miscellaneous Questions*, quest. 40; being made out from either of the terms, p or q , of the binomial, taken singly, in this manner: Separate either term, as p , into two such parts that one of them may be a cubic number, and the other part divisible by 3 without a remainder; then the cube root of the said cubic part will be one term of the root, and the other term will be the square root of the quotient arising from dividing the aforesaid third part by the first term just found. Thus if p be divided into $r^3 + 3s$, then the root is $r + \sqrt[3]{s}$.

For example, to extract the cube root of $\sqrt{108} + 10$. Suppose the part 10 to be taken: this separates into the parts 1 and 9, the former of which is a cube, and the latter divisible by 3; that is $r^3 = 1$, and $3s = 9$; hence $r = 1$, and

$s = 3$; consequently $r + \sqrt[3]{s} = 1 + \sqrt[3]{3}$ is the cube root of $\sqrt{108} + 10$ sought. Again, to use the other term $\sqrt{108}$: this divides into $\sqrt{27} + \sqrt{27}$, of which the former is a cube, and the latter divisible by 3; that is, $r^3 = \sqrt{27}$, and $3s = \sqrt{27}$; therefore $r = \sqrt{3}$, and $s = \frac{1}{3}\sqrt{27} = \sqrt{3}$ also; hence $r + \sqrt[3]{s} = \sqrt{3} + \sqrt[3]{\frac{1}{3}\sqrt{27}} = \sqrt{3} + \sqrt{\frac{1}{3}\sqrt{27}}$ the cube root, the same as before.

Bombelli's Rule for the Cube Root of the Binomial $a + \sqrt{-b}$. First find $\sqrt[3]{(a^2 + b)}$; then, by trials, search out a number c , and a square root \sqrt{d} , such that the sum of their squares $c^2 + d$ may be $=^3(a + b)$, and also $c^3 - 3cd = a$; then shall $c + \sqrt{-d}$ be the cube root of $a + \sqrt{-b}$ sought. For example, to find the cube root of $2 + \sqrt{-121}$: here $\sqrt[3]{(a^2 + b)} = \sqrt[3]{125} = 5$; then taking $c = 2$, and $d = 1$, it is $c^2 + d = 5 = ^3(a^2 + b)$ and $c^3 - 3cd =$

$= 8 - 6 = 2 = a$, as it ought; therefore $2 + \sqrt{-1}$ is the cube root of $2 + \sqrt{-121}$.—Bombelli gave also a rule for the cube root of the binomial $a + \sqrt{b}$, but it is good for nothing.

Albert Girard's Rule for the Cube Root of a Binomial. This is given in his Invention Nouvelle en l'Algèbre, and is explained by him thus: Let $72 + \sqrt{5120}$ be the given binomial whose cube root is sought.

The square of 72 the greater term is 5184, and of the less term is 5120

$$\begin{array}{r} \text{their difference } 64 \\ \text{its cube root } 4, \end{array}$$

which 4 must be the difference between the squares of the two terms of the root sought; and as the rational part 72 of the given binomial is the greater term, therefore the rational part of the required root will be the $2 + \sqrt{0}$ greater part also; consequently the root $3 + \sqrt{5}$ sought must be one of the binomials here set $3 + \sqrt{5}$, $4 + \sqrt{12}$ in the margin, where the difference of the $5 + \sqrt{20}$ squares of the terms is always 4, as required; &c.

The first, $2 + \sqrt{0}$ must be rejected, because one term of it is 0 or nothing; also because 5 exceeds the cube root of 72, or $\sqrt[3]{20}$ exceeds the cube root of $\sqrt{5120}$, therefore $5 + \sqrt{20}$, and all after it must be rejected likewise; so that the root must be either $3 + \sqrt{5}$ or $4 + \sqrt{12}$, if the given quantity has a binomial root: to know which of these is to be taken, it must be considered that the rational term of the root must measure the rational term given; and also the irrational term of the root must measure the irrational term given; then, on examination it is found that both 3 and 4 measure or divide the 72 without a remainder, but that only the $\sqrt{5}$, and not $\sqrt{12}$, measures $\sqrt{5120}$; consequently none but $3 + \sqrt{5}$ can be the cube root of the given quantity $72 + \sqrt{5120}$; which is found to answer, by cubing the said root $3 + \sqrt{5}$.

Dr. Wallis's Rule for the Cube Root of the Binomial $a + m\sqrt{b}$ or $a \pm m\sqrt{-b}$. In these forms the greatest rational part m is extracted out of the radical part, leaving only b the least radical part possible under the radical sign. He first observes that if the given quantity have a binomial root, it must be of this form $c \pm n\sqrt{b}$, with the same radical b . Then to find the value of c and n , he raises this root to the 3d power, which gives $c^3 + 3cn^2b \pm 3c^2n + n^3b \cdot \sqrt{b}$, which must be $= a \pm m\sqrt{b}$ the given quantity; hence putting the rational part of the one quantity equal to that of the other, and also the radical part of the one equal to that of the other, gives $c^3 + 3cn^2b = a$, and $3c^2n + n^3b = m$. Then assuming several values of n , from the last equation he finds the value of c ; hence if these values of c and n , substituted in the first equation, make it obtain, they are right; but if not, another value of n is assumed, and so on, till the first equation hold true. And it is to be noted that n is always an integer, or else the half of an integer. For example, if the cube root of $135 \pm \sqrt{1825}$ be required, or $135 \pm \sqrt{78}\sqrt{3}$; here $a = 135$, $m = 78$, and $b = 3$; hence $3c^2n + n^3b = m$ is $3c^2n + 3n^3 = 78$, or $c^2n + n^3 = 26$; then assuming $n = 1$, this last equation becomes $c^2 + 1 = 26$, from which c is found = 5; which values of c and n being substituted in the first equation $c^3 + 3cn^2b = a$, make $5^3 + 3 \cdot 5 \cdot 3 = 170$, but ought to be 135, showing that c is too great, and consequently n taken too little. Let n therefore be assumed = 2, so shall $2c^2 + 8 = 26$, and $c = 3$; and the first equation becomes $3^3 + 3 \cdot 3 \cdot 2^2 \cdot 3 = 27 \cdot 5 = 135$

= a as it ought, which shows that the true value of n is 2, and that of c is 3; hence then the cube root of $135 \pm \sqrt{78}\sqrt{3}$ or $c \pm \sqrt{b}$ is $3 \pm 2\sqrt{3}$ or $3 \pm \sqrt{12}$. And in like manner in the process instituted when the number in the radical is negative, as the cube root of $81 \pm 30\sqrt{-3}$, which is $\frac{3}{2} \pm \frac{1}{2}\sqrt{-3}$.

Another rule for extracting the cube root of an imaginary binomial was also given by DeMoivre, at the end of Saunderson's Algebra, by means of the trisection of an arc or angle.

Sir I. Newton's Rule for any Root of a Binomial $a \pm b$.

In his Universal Arith. is given a rule for the square root of a binomial, which is the same as the 2d by Lucas de Burgo, before given; and also a general rule for any root of a binomial, which I have not met with elsewhere; it is this: Of the given quantity $a \pm b$, let a be the greater term, and c the index of the root to be extracted. Seek the least number n whose power n^c can be divided by $a - b^{\frac{1}{c}}$ without a remainder, and let the quotient be q ; Compute $\sqrt[c]{(a + b)\sqrt{q}}$ in the nearest integer number, which call r ; divide $a \sqrt{q}$ by its greatest rational divisor, calling the quotient s : and let the nearest integer number above $\frac{r+\frac{1}{c}}{2s}$ be t : so shall $\frac{ts \pm \sqrt{(t^c - s^c) + n}}{\sqrt[2c]{q}}$ be the root sought, if the extraction of it be possible. And this rule is demonstrated by Gravesande in his commentary on Newton's Arithmetic. Many numeral examples, illustrating this rule, are given in Gravesande's Algebra, abovementioned, pa. 160, as also in Newton's Univers. Arith. pa. 53, 2d edit; and in MacLaurin's Algebra, pa. 118. Other rules may be found in Schooten's Commentary on the Geometry of Descartes, and elsewhere.

Impossible or Imaginary BINOMIAL, is a binomial which has one of its terms an impossible or an imaginary quantity: as $a + \sqrt{-b}$.

In the foregoing article are given several rules for the roots of Binomials. Dr. Maskelyne, the late Astronomer Royal, has also given a method of finding any power of an Impossible Binomial, by another like Binomial. This rule is given in his Introduction prefixed to Taylor's Tables of Logarithms, pa. 56; and is as follows.

The logarithms of a and b being given, it is required to find the power of the Impossible Binomial $a \pm \sqrt{-b^2}$, whose index is $\frac{m}{n}$, that is, to find $(a \pm \sqrt{-b^2})^{\frac{m}{n}}$ by another Impossible Binomial; and thence the value of $(a + \sqrt{-b^2})^{\frac{m}{n}} + (a - \sqrt{-b^2})^{\frac{m}{n}}$, which is always possible, whether a or b be the greater of the two.

Solution. Put $\frac{b}{a} = \tan g. z$. Then

$$(a \pm \sqrt{-b^2})^{\frac{m}{n}} = (a^2 + b^2)^{\frac{m}{2n}} \times (\cos. \frac{m}{n} z \pm \sqrt{-\sin. \frac{m}{n} z}).$$

$$\text{Hence } (a + \sqrt{-b^2})^{\frac{m}{n}} + (a - \sqrt{-b^2})^{\frac{m}{n}} = (a^2 + b^2)^{\frac{m}{2n}} \times$$

$$2 \cos. \frac{m}{n} z = (a \times \sec. z)^{\frac{m}{n}} \times 2 \cosin. \frac{m}{n} z = (b \times \operatorname{cosec}. z)^{\frac{m}{n}}$$

$\times 2 \cosin. \frac{m}{n} z$, where the first or second of these two last expressions is to be used, according as z is an extreme or mean arc; or rather, because $\frac{b}{a}$ is not only the tangent of z , but also of $z + 360^\circ, z + 720^\circ$, &c.; therefore the factor in the answer will have several values, viz,

$2 \cos \frac{m}{n} z$; $2 \cos \frac{m}{n} (z + 360^\circ)$; $2 \cos \frac{m}{n} (z + 720^\circ)$; &c; the number of which, if m and n be whole numbers, and the fraction $\frac{m}{n}$ be in its least terms, will be equal to the denominator n ; otherwise infinite.

By Logarithms. Put $\log_b b + 10 - \log_a a = \log \tan z$.

Then $\log [(a + \sqrt{-b^2})^{\frac{m}{n}} + (a - \sqrt{-b^2})^{\frac{m}{n}}] = \frac{m}{n} \times (\log b + 10 - \log \cos z) + 1.2 + 1. \log \frac{m}{n} z - 10 = \frac{m}{n} \times (1. \log \frac{m}{n} z + 10 - 1. \sin z) + 1.2 + 1. \log \frac{m}{n} z - 10$; where the first or second expression is to be used, according as z is an extreme or mean arc. Moreover by taking successively, $1. \log \frac{m}{n} z$; $1. \log \frac{m}{n} (z + 360^\circ)$; $1. \log \frac{m}{n} (z + 720^\circ)$; &c, there will arise several distinct answers to the question, agreeably to the remark made above.

BINOMIAL Curve, is a curve whose ordinate is expressed by a binomial quantity; as the curve whose ordinate is $x^a / (b + dx)^c$. Stirling, Method. Diff. p. 58.

BINOMIAL Theorem, is used to denote the celebrated theorem given by Sir I. Newton for raising a binomial to any power, or for extracting any root of it by an approximating infinite series. It was known by Stifelius, and others, about the beginning of the 16th century, how to raise the integral powers, not barely by a continued multiplication of the binomial given, but also by a table of numbers formed by Stifelius, which showed by inspection the coefficients of the terms of any power of the binomial, contained within the limits of the table; but still they could not independent of a table, and of any of the lower powers, raise any power of a binomial at once, by determining its terms one from another only, viz. the 2d term from the 1st, the 3d from the 2d, and so on as far as we please, by a general rule; and much less could they extract general algebraic roots in infinite series by any rule whatever.

For though the nature and construction of that table, which is composed of figurate numbers, was so early known, and employed in raising powers, and extracting roots; yet it was only by raising the numbers one from another by continual additions, and then taking them from the table when wanted; till Mr. Briggs first pointed out the way of raising any line in the table by itself, without any of the preceding lines; and thus teaching to raise the terms of any power of a binomial, independent of any of the other powers; and so gave the substance of the binomial theorem in words, wanting only the algebraic notation in symbols; as is shown at large at pa. 78 of the historical introduction to my Mathematical Tables. Whatever was known however of this matter, related only to pure or integral powers, no one before Newton having thought of extracting roots by infinite series. He happily discovered that, by considering powers and roots in a continued series, roots being as powers having fractional exponents, the same binomial series would equally serve for them all, whether the index should be fractional or integral, or whether the series be finite or infinite. The truth of this method however was long known only by trial in particular cases, and by induction from analogy; nor does it appear that even Newton himself ever attempted any direct proof of it: however, various demonstrations of the theorem have since been given by the more modern mathematicians, some of which are by means of the doctrine of fluxions, and others,

more legally, from the pure principles of algebra only: for a full account of which, see pa. 228, &c, of my Mathematical Tracts, vol. 1.

This theorem was first discovered by Sir I. Newton in 1669, and sent in a letter of June 13, 1676, to Mr. Oldenburg, Secretary to the Royal Society, to be by him communicated to Mr. Leibnitz; and it was in this form:

$(p + pq)^{\frac{m}{n}} = p^{\frac{m}{n}} + \frac{m}{n} aq + \frac{m-n}{2n} bq + \frac{m-2n}{3n} cq + \&c$: where $p + pq$ signifies the quantity whose root, or power, or root of any power, is to be found; p being the first term of that quantity; q the quotient of all the rest of the terms divided by that first term; and $\frac{m}{n}$ the numeral index of the power or root of the quantity $p + pq$, whether it be integral or fractional, positive or negative; and lastly $a, b, c, d, \&c$, are assumed to denote the several terms in their order as they are found, viz. $a =$ the first term $p^{\frac{m}{n}}$, $b =$ the 2d term $\frac{m}{n} aq$, $c =$ the third term $\frac{m-n}{2n} bq$, and so on. As Newton's general notation of indices was not commonly known, he takes this occasion to explain it; and then he gives many examples of the application of this theorem, one of which is the following.

Ex. 1. To find the value of $\sqrt{(c^2 + x^2)}$ or $(c^2 + x^2)^{\frac{1}{2}}$, that is, to extract the square root of $c^2 + x^2$ in an infinite series. Here $p = c^2$, $q = \frac{x^2}{c^2}$, $m = 1$, and $n = 2$; therefore $a = p^{\frac{m}{n}} = (cc)^{\frac{1}{2}} = c$, $b = \frac{m}{n} aq = \frac{x^2}{2c}$, $c = \frac{m-n}{2n} bq = \frac{-x^2}{8c^2}$, &c; therefore the root sought is $c + \frac{x^2}{2c} - \frac{x^4}{8c^2} + \frac{x^6}{16c^3} - \frac{5x^8}{128c^4} + \&c$.

A variety of other examples are also given in the same place, by which it is shown that the theorem is of universal application to all sorts of quantities whatever.—This theorem is sometimes represented in other forms, as $p^{\frac{m}{n}} \times : 1 + \frac{m}{n} q + \frac{m}{n} \cdot \frac{m-n}{2n} q^2 + \frac{m}{n} \cdot \frac{m-n}{2n} \cdot \frac{m-2n}{3n} q^3 + \&c$; which comes to the same thing. Or thus $p^{\frac{m}{n}} + \frac{m}{n} p^{\frac{m-n}{2n}} + \frac{m}{n} \cdot \frac{m-n}{2n} p^{\frac{m-2n}{3n}} + \&c$; where the binomial is $(p + r)^{\frac{m}{n}}$.

In another letter to Mr. Oldenburg, of Oct. 24, 1676, Newton explains the train of reasoning by which he obtained the said theorem, as follows: "In the beginning of my mathematical studies, when I was perusing the works of the celebrated Dr. Wallis (see his Arith. of Infinites, prop. 118, and 121, also his Algebra, chap. 82), and considering the series by the interpolation of which he exhibits the area of the circle and hyperbola; for instance, in this series of curves, whose common base or axis is x , and the ordinates respectively $(1 - xx)^{\frac{1}{2}}$, $(1 - xx)^{\frac{3}{2}}$, $(1 - xx)^{\frac{5}{2}}$, $(1 - xx)^{\frac{7}{2}}$, &c; I perceived that if the areas of the alternate curves, which are

$$x - \frac{1}{4}x^3,$$

$$x - \frac{3}{4}x^3 + \frac{1}{2}x^5,$$

$$x - \frac{3}{2}x^3 + \frac{3}{2}x^5 - \frac{1}{2}x^7,$$

&c; could be interpolated, we should be able to obtain the areas of the intermediate ones; the first of which, $(1 - xx)^{\frac{1}{2}}$, is the area of the circle: now in order to this, it appeared that in all the series the first term was x ; that the 2d terms $\frac{3}{4}x^3$, $\frac{1}{2}x^5$, $\frac{3}{2}x^5$, $\frac{1}{2}x^7$, &c, were in arithmetical

progression; and consequently that the first two terms of all the series to be interpolated would be

$$x - \frac{1}{3}x^3, \quad x - \frac{2}{3}x^3, \quad x - \frac{3}{3}x^3, \text{ &c.}$$

Now for the interpolation of the rest, I considered that the denominators, 1, 3, 5, 7, &c., were in arithmetic progression; and that therefore only the numerical coefficients of the numerators were to be investigated. But these in the alternate areas, which are given, were the same with the figures of which the several powers of 11 consist; viz, of 11⁰, 11¹, 11², 11³, &c.; that is,

- the first 1,
- the second 1, 1
- the third 1, 2, 1
- the fourth 1, 3, 3, 1
- the fifth 1, 4, 6, 4, 1
- &c.

I enquired therefore how, in these series, the rest of the terms may be derived from the first two being given; and I found that by putting m for the 2d figure or term, the rest would be produced by the continued multiplication of the terms of this series,

$$\frac{m-0}{1} \times \frac{m-1}{2} \times \frac{m-2}{3} \times \frac{m-3}{4} \times \frac{m-4}{5} \text{ &c.}$$

For instance, if the 2d term $m = 4$; then shall $4 \times \frac{m-1}{2}$, or 6, be the 3d term; and $6 \times \frac{m-2}{3}$, or 4, the 4th term; and $4 \times \frac{m-3}{4}$ or 1, the 5th term; and $1 \times \frac{m-4}{5}$, or 0, the 6th; which shows that in this case the series terminates.

This rule therefore I applied to the series to be interpolated. And since, in the series for the circle, the 2d term was $\frac{1}{3}x^3$ I put $m = \frac{1}{2}$, which produced the terms

$$\frac{1}{2} \times \frac{\frac{1}{2}-1}{2} \text{ or } -\frac{1}{8}; \quad -\frac{1}{8} \times \frac{\frac{1}{2}-2}{3} \text{ or } +\frac{1}{16}; \quad +\frac{1}{16} \times \frac{\frac{1}{2}-3}{4} \text{ or } -\frac{5}{128}; \quad \text{and so on ad infinitum.}$$

And hence I found that the required area of the circular segment is

$$x - \frac{1}{3}x^3 - \frac{1}{5}x^5 - \frac{1}{7}x^7 - \frac{1}{9}x^9 - \text{ &c.}$$

And in the same manner might be produced the interpolated areas of the other curves: as also the area of the hyperbola and the other alternates in this series

$$(1+xx)^{\frac{1}{2}}, (1+xx)^{\frac{1}{3}}, (1+xx)^{\frac{2}{3}}, (1+xx)^{\frac{3}{2}}, \text{ &c.}$$

And in the same way also may other series be interpolated, but that too if they should be taken at the distance of two or more terms.

This was the way then in which I first entered upon these speculations; which I should not have remembered, but that in turning over my papers a few weeks since, I chanced to turn my eyes on those relating to this matter.

Having proceeded so far, I considered that the terms $(1-xx)^{\frac{1}{2}}, (1-xx)^{\frac{1}{3}}, (1-xx)^{\frac{2}{3}}, (1-xx)^{\frac{3}{2}}, \text{ &c.}$, that is,

$$1 - x^2$$

$$1 - 2x^2 + x^4$$

$$1 - 3x^2 + 3x^4 - x^6, \text{ &c.}$$

might be interpolated in the same manner as the areas generated by them: and for this, nothing more was required but to omit the denominators 1, 3, 5, 7, &c., in the terms expressing the areas; that is, the coefficients of the terms of the quantity to be interpolated $(1-xx)^{\frac{1}{2}}$, or $(1-xx)^{\frac{1}{3}}$, or generally

$(1-xx)^m$, will be produced by the continued multiplication of the terms of this series

$$m \times \frac{m-1}{2} \times \frac{m-2}{3} \times \frac{m-3}{4} \text{ &c.}$$

Thus, for example, there would be found

$$(1-xx)^{\frac{1}{2}} = 1 - \frac{1}{2}x^2 - \frac{1}{8}x^4 - \frac{1}{16}x^6 \text{ &c.}$$

$$(1-xx)^{\frac{1}{3}} = 1 - \frac{1}{3}x^2 + \frac{1}{2}x^4 + \frac{1}{16}x^6 \text{ &c.}$$

$$(1-xx)^{\frac{1}{2}} = 1 - \frac{1}{2}x^2 - \frac{1}{8}x^4 - \frac{1}{32}x^6 \text{ &c.}$$

Thus then I discovered a general method of reducing radical quantities into infinite series, by the theorem which I sent in the beginning of the former letter, before I knew the same by the extraction of roots.

But having discovered that way, this other could not long remain unknown: for to prove the truth of those operations, I multiplied

$1 - \frac{1}{2}x^2 - \frac{1}{8}x^4 - \frac{1}{32}x^6$, by itself, and the product was $1 - x^2$, all the rest of the terms vanishing after these, in infinitum. In like manner,

$1 - \frac{1}{3}x^2 - \frac{1}{8}x^4 - \frac{1}{32}x^6$, twice multiplied by itself, produced $1 - x^2$. But as this was a certain proof of those conclusions, so I was naturally led to try conversely whether these series, which were thus known to be the roots of the quantity $1 - x^2$, could not be extracted out of it after the manner of arithmetic; and upon trial I found it to succeed. The process for the square root is here set down

$$1 - x^2(1 - \frac{1}{2}x^2 - \frac{1}{8}x^4 - \frac{1}{32}x^6 \text{ &c.})$$

1

$$0 - x^2$$

$$- x^2 + \frac{1}{2}x^4$$

$$-\frac{1}{4}x^4$$

$$-\frac{1}{4}x^4 + \frac{1}{8}x^6 + \frac{1}{32}x^8$$

$$-\frac{1}{8}x^6 - \frac{1}{64}x^8$$

These methods being found, I laid aside the other way by interpolation of series, and used these operations only as a more genuine foundation. Neither was I ignorant of the reduction by division, which is so much easier." See Collins's Commercium Epistolicum.

And this is all the account that Newton gives of the invention of this theorem, which is engraved on his monument in Westminster Abbey, as one of his greatest discoveries.

Francis Maseres, Esq. (Cursitor Baron of the Exchequer) has communicated the following observations on the Binomial theorem, and its demonstration; viz, About the year 1666 the celebrated Sir Isaac Newton discovered that, if m were put for any whole number whatsoever, the coefficients of the terms of the m th power of $1+x$ would be

$$1, \frac{m}{1}, \frac{m}{1} \cdot \frac{m-1}{2}, \frac{m}{1} \cdot \frac{m-1}{2} \cdot \frac{m-2}{3}, \text{ &c.}$$

till we come to the term $\frac{m-(m-1)}{m}$, which will be the last term. But by what particular means he discovered this proposition, he has not told us, nor has he even attempted to give a demonstration of it. Dr. John Wallis, of Oxford, informs us (in his Algebra, chap. 85, pa. 319) that he had endeavoured to find this manner of generating these coefficients one from another, but without success;

and he was greatly delighted with the discovery, when he found that Mr. Newton had made it. But he likewise has omitted to give a demonstration of it, as well as Sir Isaac Newton; and probably he did not know how to demonstrate it.

Newton, after having discovered this rule for generating the coefficients of the powers of $1 + x$ when the indices of those powers were whole numbers, conjectured that the same might possibly obtain also when the indices were fractions. He therefore resolved to try whether it would or not, by applying it to such indices in a few easy instances, and particularly to those of $\frac{1}{2}$ and $\frac{1}{3}$, which, if the rule served in the case of fractional indices, would enable him to find series equal to the values of $(1+x)^{\frac{1}{2}}$ and $(1+x)^{\frac{1}{3}}$, or the square-root and the cube-root of the binomial quantity $1+x$. And, when he had in this manner obtained a series for $(1+x)^{\frac{1}{2}}$, which he suspected to be equal to $(1+x)^{\frac{1}{2}}$, or the square root of $1+x$, he multiplied the said series into itself, and found that the product was $1+x$; and when he had discovered in like man-

nner a series for $(1+x)^{\frac{1}{3}}$ he multiplied the same twice into itself, and found that the product was $1+x$; and thence he concluded that the former series was really equal to the square-root of $1+x$, and that the latter series was really equal to its cube-root. And from these and a few more such trials, in which he found the rule to answer, he concluded universally that the rule was always true, whether the index m stood for a whole number or a fraction of any kind, as $\frac{1}{2}, \frac{2}{3}, \frac{3}{2}, \frac{5}{3}, \frac{2}{5}$, or, in general, $\frac{p}{q}$.

After the discovery of this rule by Sir Isaac Newton, and the publication of it by Dr. Wallis, in his Algebra, chap. 85, in the year 1685, (which I believe was the first time it was published to the world at large, though it was inserted in Sir Isaac Newton's first letter to Mr. Oldenburg, the secretary to the Royal Society, dated June 13, 1676, and the said letter was shown to Mr. Leibnitz, and probably to some other of the learned mathematicians of that time) it remained for some years without a demonstration, either in the case of integral powers or of roots. At last however it was demonstrated in the case of integral powers by means of the properties of the figurate numbers, by that learned, sagacious, and accurate mathematician Mr. James Bernoulli, in the 3d chapter of the 2d part of his excellent treatise De Arte Conjectandi, or, On the Art of forming reasonable Conjectures concerning Events that depend on Chance; which appears to me to be by far the best-written treatise on the doctrine of Chances that has yet been published, though M. Demoivre's book on the same subject may have carried the doctrine something further. This treatise of James Bernoulli's was not published till 8 years after his death, which happened in August 1705; but there is reason to think that it was composed in the latter 5 or 6 years of the preceding century, and even that some parts of it, or some of the propositions inserted therein, had been discovered by the author in the years 1689, 1690, 1691, and 1692. For the first part of his very curious tract, entitled, Positiones Arithmeticae de Seriebus Infinitis, was published at Basil or Basle in Switzerland in the year 1689; and the second part of the said Positiones (in the 19th Position of which those properties of the figurate numbers from which the binomial theorem may be deduced, are set down) was published at the same place in the year 1692. But the demonstrations of those properties of the figurate numbers, and of the binomial theorem, which depends upon them, were never I believe communicated to the public till the year 1713, when the author's posthumous treatise De Arte Conjectandi made

its appearance. These demonstrations are founded on clear and simple principles, and afford as much satisfaction as can well be expected on this subject. But the full display and explanation of these principles, and the deduction of the said properties of the figurate numbers, and ultimately of the Binomial theorem, from them, is a matter of considerable length. It will therefore not be improper to give a shorter proof of the truth of this important theorem, that shall not require a previous knowledge of the properties of the figurate numbers, but yet shall be equally conclusive with that which is derived from those properties. Now this may be done in the manner following.

Let us suppose that the coefficients of the terms of the first six powers of the Binomial quantity $1+x$ have been found, upon trial, to be such as would be produced by the general expressions

$$1, \frac{m}{1}, \frac{m}{1} \cdot \frac{m-1}{2}, \frac{m}{1} \cdot \frac{m-1}{2} \cdot \frac{m-2}{3}, \text{ &c,}$$

by substituting in them first 1, then 2, then 3, then 4, then 5, and lastly 6 instead of m . This may easily be tried by first raising $1+x$ to the 6th power, by repeated multiplications in the common way, and afterwards finding the terms of the powers by means of the said general expressions above; which will be found to produce the very same terms as arose from the multiplications. After these trials we shall be sure that those general expressions are the true values of the coefficients of the powers of $1+x$ at least in the said first six powers. And it will therefore only remain to be proved that, since the rule is true in the said first six powers, it will also be true in the next following, or the 7th power, and consequently in the 8th, 9th, and 10th powers, and in all higher powers whatsoever.

Now, if the coefficients of the 1st, 2d, 3d, 4th, and other following terms of $1+x^m$ be denoted by the letters $a, b, c, d, \text{ &c}$, respectively, it is evident from the nature of multiplication, that the coefficients of the 1st, 2d, 3d, 4th, and other following terms of the next higher power of $1+x$, to wit, $1+x^{m+1}$ will be equal to $a, a+b, b+c, c+d, \text{ &c}$, respectively, or to the sums of every two contiguous coefficients of the terms of the preceding series which is $= 1+x^m$. This will appear from the operation of multiplication, which is as follows:

$$\begin{aligned} &a + bx + cx^2 + dx^3 + ex^4 + \text{ &c} \\ &\quad 1 + x \\ &\hline a + bx + cx^2 + dx^3 + ex^4 + \text{ &c} \\ &\quad + ax + bx^2 + cx^3 + dx^4 + \text{ &c}. \end{aligned}$$

Therefore, if $1+x^m$ be equal to the series

$$a + bx + cx^2 + dx^3 + ex^4 + \text{ &c},$$

then $1+x^{m+1}$ will be equal to the series

$$a + a + b \cdot x + b + c \cdot x^2 + c + d \cdot x^3 + \text{ &c.}$$

Now let n be $= m+1$. We shall then have to prove that, if the coefficients $a, b, c, d, \text{ &c}$, be respectively equal to $1, \frac{m}{1}, \frac{m}{1} \cdot \frac{m-1}{2}, \frac{m}{1} \cdot \frac{m-1}{2} \cdot \frac{m-2}{3}, \text{ &c.}$ the coefficients $a, a+b, b+c, c+d, \text{ &c.}$ will be respectively equal to $1, \frac{n}{1}, \frac{n}{1} \cdot \frac{n-1}{2}, \frac{n}{1} \cdot \frac{n-1}{2} \cdot \frac{n-2}{3}, \text{ &c.}$

And to do which, there is nothing more required than to collect together every two terms of the former of these two series, and then substitute into these sums, n instead

of $m + 1$, when there will immediately come out the terms of the latter series, as above, viz,

$$\frac{1}{1+x}^n = 1 + \frac{n}{1}x + \frac{n(n-1)}{2}x^2 + \text{ &c. q. e. d.}$$

For several other demonstrations of the Binomial Theorem, see my new Tracts, vol. 1, pa. 228, &c.

BIPARTIENT, is a number that divides another into two equal parts without a remainder. So 2 is a bipartient to 4, and 5 a bipartient to 10.

BIPARTITION, is a division into two equal parts.

BIQUADRATIC, or **BIQUADRATIC Power**, is the squared square, or 4th power of any number or quantity. Thus 16 is the biquadrate or 4th power of 2, or it is the square of 4 which is the 2d power of 2.

BIQUADRATIC Root, of any quantity, is the square root of the square root, or the 4th root of that quantity. So the biquadratic root of 16 is 2, and the biquadratic root of 81 is 3.

BIQUADRATIC Equation, is that which rises to 4 dimensions, or in which the unknown quantity rises to the 4th power; as $x^4 + ax^3 + bx^2 + cx + d = 0$.

Any biquadratic equation may be conceived to be generated or produced from the continual multiplication of four simple equations, as $(x - p) \times (x - q) \times (x - r) \times (x - s) = 0$; or from that of two quadratic equations, as $(x^2 + px + q) \times (x^2 + rx + s) = 0$; or, lastly, from that of a cubic and a simple equation, as $(x - p) \times (x^3 + qx^2 + rx + s) = 0$; which was the invention of Harriot. And on the contrary, a biquadratic equation may be resolved into four simple equations, or into two quadratics, or into a cubic and a simple equation, having all the same roots with it.

1. *Ferrari's Method for Biquadratic Equations.*

The first resolution of a biquadratic equation was given in Cardan's Algebra, chap. 39, being the invention of his pupil and friend Lewis Ferrari, about the year 1540. This is effected by means of a cubic equation, and is indeed a method of depressing the biquadratic equation to a cubic, which Cardan demonstrates, and applies in a great variety of examples. The principle is very general, and consists in making one side of the equation a square, by help of some multiples or parts of its own terms and an assumed unknown quantity; which it is always easy to do; and then the other side is made to be a square also, by assuming the product of its 1st and 3d terms equal to the square of half the 2d term; for it consists only of three terms, or three different denominations of the original letter; then this equality will determine the value of the assumed quantity by a cubic equation: other circumstances depend on the artist's judgment. But the method will be farther explained by the following examples, extracted from Cardan's book.

Ez. 1. Given $x^4 + 6x^2 + 36 = 60x$, to be resolved.

Add $6x^2$ to both sides of the equation, so shall

$$x^4 + 12x^2 + 36 \text{ or } (x^2 + 6)^2 = 6x^2 + 60x.$$

Assume y_2 , and add $(x^2 + 6)2y + y^2$ to both sides, then is $(x^2 + 6)^2 + 2y(x^2 + 6) + y^2 = 6x^2 + 60x + 2y(x^2 + 6) + y^2$, or $(x^2 + 6 + y)^2 = (6 + 2y)x^2 + 60x + 12y + y^2$.

Make now the 1st \times 3d term $= \frac{1}{4}$ sq. 2d, this gives $(6 + 2y) \cdot (12y + y^2) x^2 = 900x^2$, or $y^3 + 15y^2 + 36y = 450$; and hence $y = \sqrt[3]{(287\frac{1}{2}) + \sqrt{80449\frac{1}{4}}} + \sqrt[3]{(287\frac{1}{2}) - \sqrt{80449\frac{1}{4}}} - 5$. From which x may be found by a quadratic equation.

VOL. I.

For, because $(6 + 2y) \cdot (12y + y^2) \cdot x^2 = 900x^2$, $(6 + 2y) \cdot x^2 + 60x + 12y + y^2$ becomes a square, whose root is evidently equal to $x\sqrt{(6 + 2y)^2 + (12y + y^2)}$; and since $(x^2 + 6 + y)^2 = (6 + 2y)x^2 + 60x + 12y + y^2$, their roots are also equal, that is $x^2 + 6 + y = x\sqrt{(6 + 2y)^2 + (12y + y^2)}$, a quadratic equation.

Ez. 2. Given $x^4 = x + 2$.

Before applying Ferrari's method to this example, Cardan resolves it by another way as follows: subtract 1, from both sides of the equation, then is $x^4 - 1 = x + 1$; divide by $x + 1$, then is $x^3 - x^2 + x - 1 = 1$, or $x^3 + x = x^2 + 2$; and hence $x = \sqrt[3]{(\sqrt{\frac{2241}{2916}} + \frac{47}{54})} - \sqrt[3]{(\sqrt{\frac{2241}{2916}} - \frac{47}{54})} + \frac{1}{3}$.

But to resolve it by Ferrari's rule:

Because $x^4 = x + 2$; therefore $x^4 + 2yx^3 + y^2$ or $(x^2 + y)^2 = 2yx^2 + x + (2 + y^2)$; hence $2y^2 + 4y = \frac{1}{4}$, or $y^2 + 2y = \frac{1}{8}$; and the root is $y = \sqrt[3]{(\sqrt{\frac{2075}{6912}} + \frac{1}{10})} - \sqrt[3]{(\sqrt{\frac{2075}{6912}} - \frac{1}{16})}$:

by means of which x is found by a quadratic equation.

Ez. 3. Given $x^4 + 32x^2 + 16 = 48x$.—Add 240, then $x^4 + 32x^2 + 256$ or $(x^2 + 16)^2 = 48x + 240$; complete square again, then $(x^2 + 16)^2 + 2y \cdot (x^2 + 16) + y^2 = 2yx^2 + 48x + (y^2 + 32y + 240)$; make the last side a sq. by the rule, which gives $y^3 + 32y^2 + 240y = 24 \times 12 = 288$. Put now $z = y + 10\frac{2}{3}$, and the last transforms to $z^3 = 101\frac{2}{3} + 420\frac{16}{27}$; then the value of z found from this, gives the value of y , and hence the value of x as before.

2. *Descartes's Rule for Biquadratic Equations.*

Another solution was given of biquadratic equations by Descartes, in the 3d book of his Geometry. In this solution he resolved the given biquadratic equation into two quadratics, by means of a cubic equation, in this manner: First, let the 2d term, or 3d power be taken away out of the equation, after which it will stand thus,

$x^4 + px^3 + qx + r = 0$. Find y in this cubic equation $y^3 + 2py^2 + p^2 - 4r = 0$; and then the values of $\begin{cases} x^2 - yx + \frac{1}{4}y^2 + \frac{1}{4}p + \frac{q}{2y} \\ x^2 + yx + \frac{1}{4}y^2 + \frac{1}{4}p - \frac{q}{2y} \end{cases} = 0$, so shall these values of x be the roots of the given biquadratic equation.

Ez. Let the equ. be $x^4 - 17x^2 - 20x - 6 = 0$.

Here $p = -17$, $q = -20$, and $r = -6$; and the cubic equ. is $y^3 - 34y^2 + 313y^2 - 400 = 0$, the root of which is $y^2 = 16$, or $y = 4$; hence the two qua- $\begin{cases} x^2 - 4x - 3 = 0 \\ x^2 + 4x + 2 = 0, \end{cases}$ dratics are the four roots of which are $2 \pm \sqrt{7}$ and $-2 \pm \sqrt{2}$.

3. *Euler's Method for Biquadratic Equations.*

The celebrated Leonard Euler has also given, in the 6th volume of the Petersburg Ancient Commentaries, for the year 1738, an ingenious and general method for resolving equations of all degrees, by means of the equation of the next lower degree, and among them that of the biquadratic equation by means of the cubic; and this last was also given more at large in his treatise of Algebra, translated from the German into French in 1774, in 2 volumes 8vo. The method is this: Let $x^4 - ax^2 - bx - c = 0$, be the

given biquadratic equation, wanting the 2d term. Take $f = \frac{1}{2}a$, $g = \frac{1}{16}aa + \frac{1}{4}c$, and $h = \frac{1}{64}bb$; with which values of f , g , h , form the cubic equation $s^3 - fs^2 + gs - h = 0$. Then find the three roots of this cubic equation, and let them be called p , q , r . So shall the four roots of the proposed biquadratic be these following, viz;

When $\frac{1}{8}b$ is positive:

- | | |
|---------------------------------------|----------------------------------|
| 1st. $\sqrt{p} + \sqrt{q} + \sqrt{r}$ | When $\frac{1}{8}b$ is negative: |
| $\sqrt{p} + \sqrt{q} - \sqrt{r}$ | $\sqrt{p} + \sqrt{q} + \sqrt{r}$ |
| $\sqrt{p} + \sqrt{q} + \sqrt{r}$ | $\sqrt{p} - \sqrt{q} + \sqrt{r}$ |
| $\sqrt{p} - \sqrt{q} + \sqrt{r}$ | $\sqrt{p} + \sqrt{q} + \sqrt{r}$ |
| 4th. $\sqrt{p} - \sqrt{q} - \sqrt{r}$ | $\sqrt{p} - \sqrt{q} - \sqrt{r}$ |

Ex. Let the equ. be $x^4 - 25x^2 + 60x - 36 = 0$.

Here $a = 25$, $b = -60$, and $c = 36$;

therefore $f = \frac{25}{2}$, $g = \frac{625}{16} + 9 = \frac{769}{16}$, and $h = \frac{225}{4}$.

Consequently the cubic equation will be

$$z^3 - \frac{25}{2}z^2 + \frac{769}{16}z - \frac{225}{4} = 0.$$

The three roots of which are

$z = \frac{9}{4} = p$, and $z = 4 = q$, and $z = \frac{25}{4} = r$; and the roots of these are $\sqrt{p} = \frac{3}{2}$, $\sqrt{q} = 2$ or $\frac{1}{2}$, $\sqrt{r} = \frac{5}{2}$.

Hence, as the value of $\frac{1}{8}b$ is negative, the four roots are

- 1st. $x = \frac{3}{2} + \frac{3}{2} - \frac{5}{2} = 1$,
- 2d. $x = \frac{3}{2} - \frac{3}{2} + \frac{5}{2} = 2$,
- 3d. $x = -\frac{3}{2} + \frac{3}{2} + \frac{5}{2} = 3$,
- 4th. $x = -\frac{3}{2} - \frac{3}{2} - \frac{5}{2} = -6$.

4. Simpson's Rule for Biquadratic Equations.

Mr. Simpson gave a general rule for the solution of biquadratic equations, having all its terms, in the 2d edit. of his Algebra, pa. 150, published in 1755, in which the given equation is also resolved by means of a cubic equation, as well as the two former ways; and it is investigated on the principle, that the given equation is equal to the difference between two squares; being indeed a kind of generalization of Ferrari's method.

Thus, he supposes the given equation, viz,

$$x^4 + px^2 + qx^2 + rx + s = (x^2 + \frac{1}{2}px + a)^2 - (bx + c)^2;$$

then from a comparison of the like terms, the values of the assumed letters are found, and the final equation becomes

$$\alpha^3 - \frac{1}{2}q\alpha^2 + k\alpha - \frac{1}{2}l^2 = 0,$$

where $k = \frac{1}{4}pr - s$, and $l = \frac{1}{4}r^2 + s \cdot (\frac{1}{4}p^2 - q)$.

The value of α being found in this cubic equation, those of b and c will be had from their general values, viz,

$b = \sqrt{(2a + \frac{1}{4}p^2 - q)}$, and $c = \frac{pa - r}{2b}$. Hence, finally, the root x will be obtained from the assumed equation $(x^2 + \frac{1}{2}px + a)^2 - (bx + c)^2 = 0$, or $x^2 + \frac{1}{2}px + a = \pm bx \pm c$ (which always is the case when the value of x is taken such, that the given biquadratic becomes equal to nothing), in four several values.

Ex. Given the equ. $x^4 - 6x^2 - 58x^2 - 114x - 11 = 0$. Here $p = -6$, $q = -58$, $r = -114$, and $s = -11$, whence

k or $\frac{1}{4}pr - s = 182$, l or $\frac{1}{4}r^2 + s \cdot (\frac{1}{4}p^2 - q) = 2512$; and therefore the cubic equation becomes

$$\alpha^3 + 29\alpha^2 + 182\alpha - 1256 = 0,$$

the root of which is $\alpha = 4$.

Hence then b or $\sqrt{2a + \frac{1}{4}p^2 - q} = \sqrt{75}$, and c or $\frac{pa - r}{2b} = \sqrt{27}$:

then the quadratic equation becomes

$$x^2 - 3x + 4 = \pm x\sqrt{75} \pm \sqrt{27};$$

which solved gives

$$x = \frac{1}{2} \pm \frac{2}{2}\sqrt{3} + \sqrt{(17 \pm 11\frac{1}{2}\sqrt{3})},$$

$$\text{or } = \frac{1}{2} \pm \frac{2}{2}\sqrt{3} - \sqrt{(17 \pm 11\frac{1}{2}\sqrt{3})},$$

exhibiting all the 4 roots of the given equation according to the variations of the signs.

Mr. Simpson here subjoins an observation which is totally erroneous, viz, that "The value of α , in this equation, will be commensurate and rational (and therefore the easier to be discovered), not only when all the roots of the given equation are commensurate, but when they are irrational and even impossible; as will appear from the example subjoined." It must indeed appear singular that he should have adduced such a reason for the proof of a proposition without any foundation; and it is wonderful that he fell upon no examples that refuted it, as the instances in which it holds true, are so few, in comparison with the number of those in which it fails.

By methods similar to most of the foregoing ones, Dr. Waring gave very general investigations of such rules for biquadratics, in his *Meditations Algebraicæ*, published in 1770.

Note. In any biquadratic equation having all its terms, if $\frac{1}{8}$ of the square of the coefficient of the 2d term be greater than the product of the coefficients of the 1st and 3d terms, or $\frac{3}{8}$ of the square of the coefficient of the 4th term be greater than the product of the coefficients of the 3d and 5th terms, or $\frac{5}{8}$ of the square of the coefficients of the 3d term greater than the product of the coefficients of the 2d and 4th terms; then all the roots of that equation will be real and unequal; but if either of the said parts of those squares be less than either of those products, the equation will have imaginary roots.

For the construction of biquadratic equations, see CONSTRUCTION. See also Descartes's Geometry, with the Commentaries of Schooten and others; Baker's Geometrical Key; Slusius's Mesolabium; L'Hospital's Conic Sections; Folius's Elementa Matheseos; &c.

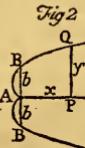

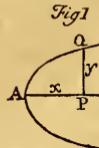

BIQUADRATIC Parabola, a curve of the 3d order, having two infinite legs, and expressed by one of these three equations, viz,

$$ax^2 = y^2, \text{ as in fig. 1,}$$

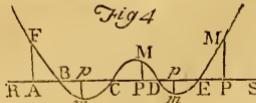

$$ax^2 = y^2 - ab^2, \text{ as in fig. 2,}$$

$$ax^2 = y^2 - (a+b) \cdot y^2 - aby^2, \text{ as in fig. 3;}$$

where $x = AP$ the absciss, $y = PQ$ the ordinate, $b = AB$, $c = AC$, and $a =$ a certain given quantity.

But the most general equation of this curve is the following, which belongs to fig. 4, viz,

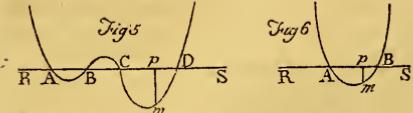

$$ay = x^4 + bx^3 + cx^2 + dx + e;$$

where $x = AP$ or AP' the absciss, and $-y$ or $+y$ is the ordinate pm or pm' , also a , b , c , d , e , are constant quantities; the beginning of the absciss being at any point A on the indefinite line AP .

But if the beginning of the absciss A be at the point where this line intersects the curve, as in fig. 5, then the

nature of the curve will be defined by this equation $a \times pm = ap \times bp \times cp \times dp$, wherever the point p is taken in the infinite line rs .

When the curve has no serpentine part, as fig. 6, the equation is more simple, being in this case barely $a \times pm = ap^2 \times pb^2$. See CURVE-LINES, and GEOMETRICAL LINES.

B I Q U I N T I L E, an aspect of the planets when the distance between them is 144 degrees, or twice the 5th part of 360 degrees.

B I S E C T I O N, or B I S S E C T I O N, the division of a quantity into two equal parts, otherwise called bipartition.

B I S S E X T I L E, or Leap-year, a year consisting of 366 days, and happening every 4th year, in consequence of the addition of 1 day to the month of February, when that month consists of 29 days. And this is done to compensate for the 6 hours which the sun takes up nearly in his course, more than the 365 days commonly allowed for it in other years.

The day thus added was by Julius Caesar appointed to be the day before the 24th of February, which among the Romans was the 6th of the calends, and which on this occasion was reckoned twice; whence it was called the Bissextile.

By the statute De anno bissextile, 21 Hen. 3d, to prevent misunderstandings, the intercalary day and that next before it are to be accounted as one day.

To find what year of the period any given year is; divide the given year by 4; then if 0 remains, it is leap-year; but if any thing remain, the given year is so many after leap-year.

But the astronomers concerned in reforming the calendar in 1582, by order of Pope Gregory the 13th, observing that in 4 years the bissextile added 44 minutes more than the sun spent in returning to the same point of the ecliptic; and computing that in 133 years these supernumerary minutes would form a day; to prevent any changes being thus insensibly introduced into the seasons, directed, that in the course of 400 years there should be three sextiles retrenched; so that every centesimal year (which is a leap-year according to the Julian account), is a common year in the Gregorian account, unless the number of centuries can be divided by 4 without a remainder. So 1600 and 2000 are bissextile; but 1700, 1800, and 1900 are common years.

The Gregorian computation has been received in most foreign countries ever since the reformation of the calendar in 1582; excepting some northern countries, as Russia, &c. And by act of parliament, passed in 1751, it commenced in all the dominions under the crown of Great Britain in the year following; it being ordered by that act that the natural day next following the 2d of September, should be accounted the 14th; omitting the intermediate 11 days of the common calendar. The supernumerary day, in leap-years, being added at the end of the month of February, and called the 29th of that month.

The centesimal year 1800 having been a common year, instead of a bissextile, from that time there are now 12 days difference between the old and new style, and so will

continue till the year 1900, when the difference between will be one day more, and so on, at every centesimal year which is not exactly divisible by 4.

B L A C K, a colour so called, or rather a privation of all colour. This, it appears, arises from such a peculiar texture and situation of the superficial parts of a black body, that they absorb all or most of the rays of light, reflecting little or none to the eye; and hence it happens that black bodies, thus imbibing the rays, are always found to be hotter than those of a lighter colour. Dr. Franklin observes that black clothes heat more, and dry sooner in the sun than white clothes; that therefore black is a bad colour for clothes in hot climates; but a fit colour for the linings of ladies' summer hats; and that a chimney painted black, when exposed to the sun, will draw more strongly. Franklin's Experim. &c.—Dr. Watson, the present bishop of Llandaff, covered the bulb of a thermometer with a black coating of Indian ink, and the consequence was that the mercury rose 10 degrees higher. Philos. Trans. vol. 63, pa. 40; and the same thing has since been evinced by the experiments of Mr. Leslie and other philosophers.—And a virtuoso of some credit assured Mr. Boyle, that in a hot climate by blacking the shells of eggs, and exposing them to the sun, he had seen them thus well roasted.

B L A C K N E S S, the quality of a black body, as to colour; arising from its stifling or absorbing the rays of light, and reflecting little or none. In which sense it stands directly opposed to whiteness; which consists in such a texture of parts, as indifferently reflects all the rays thrown upon it, of whatever colour they may be.

D e s c a r t e s, it appears, first rightly distinguished these causes of black and white, though he might be mistaken with respect to the general nature of light and colours.—Sir Isaac Newton shows, in his Optics, that to produce black colours, the corpuscles must be smaller than for exhibiting those other colours; because, where the sizes of the component particles of a body are greater, the light reflected is too much for constituting this colour; but when they are somewhat smaller than is requisite to reflect the white, and very faint blue of the first order, they will reflect so small a portion of light, as to appear intensely black; and yet they may perhaps reflect it variously to and fro within them so long, till it be stifled and lost.

B L A G R A V E (J O H N), an eminent mathematician, who
2 11 2

flourished in the 16th and 17th centuries. He was the second son of John Blagrave, of Bulmarsh-court, near Sunning in Berkshire, descended from an ancient family in that country. From a grammar-school at Reading he was sent to St. John's-college in Oxford, where he applied himself chiefly to the study of mathematics. From hence he retired to his patrimonial seat of Southcote-lodge, near Reading, where he spent the rest of his life, in a retired manner, without marrying, that he might have more leisure to pursue his favourite studies; which he did with great application and success. After a life thus spent in study, and in acts of benevolence to all around him, he died in the year 1611; and was buried at Reading in the church of St. Lawrence, where a sumptuous monument was erected to his memory.

He left the bulk of his fortune to the posterity of his three brothers, which were very numerous. There have been mentioned various acts of his beneficence in private life, for the encouragement of learning, the reward of merit, and the relief of distress. Some of these were the result of a quaint, humorous disposition, discovered chiefly in his legacies. One of these was 10 pounds left to be annually disposed of in the following manner: On Good-friday, the churchwardens of each of the three parishes of Reading send to the town-hall "one virtuous maid who has lived five years with her master;" there, in the presence of the magistrates, these three virtuous maids throw dice for the 10 pounds. The year following the two losers are returned with a fresh one, and again the third year, till each has had three chances. He also left an annuity to 80 poor widows, who should attend annually on Good-friday also, and hear a sermon, for the preaching of which he left 10 shillings to the minister. He took care also for the maintenance of his servants, rewarding their diligence and fidelity, and providing amply for their support. Thus it appears he was not more remarkable for his scientific knowledge, than for his generosity and philanthropy. His works are,

1. A Mathematical Jewel. Lond. 1585, folio.
2. Of the Making and Use of the Familiar Staff. Lond. 1590, 4to.
3. Astrolabium Uranicum Generale. Lond. 1596, 4to.
4. The Art of Dyalling. Lond. 1609, 4to.

BLAIR (JOHN), an eminent chronologist, was born and educated at Edinburgh. Afterward, coming to London, he was for some time usher of a school in Hedge-lane. In 1754 he first published *The Chronology and History of the World, from the Creation to the year of Christ 1753*, illustrated in 56 tables. In 1755 he was elected a fellow of the Royal Society, and in 1761 of the Society of Antiquaries. In 1756 he published a 2d edition of his Chronological Tables, and in 1768 an improved edition of the same, with the addition of 14 Maps of Ancient and Modern Geography, for illustrating the Tables of Chronology and History; to which is prefixed a Dissertation on the Progress of Geography. In 1757 he was appointed chaplain to the Princess Dowager of Wales, and Mathematical Tutor to the Duke of York; whom he attended in 1763 in a tour to the continent, from which they returned the year after. Dr. Blair had successively several good church preferments: as a prebendal stall at Westminster, the vicarage of Hinckley, and the rectory of Burton Coggles in Lincolnshire, all in 1761; the vicarage of St. Bride's in London, in 1771, in exchange for that of Hinckley; the rectory of St. John the Evangelist in Westminster, in 1776,

in exchange for the vicarage of St. Bride's; in the same year the rectory of Horton near Colebrooke, Bucks. Dr. Blair died the 24th of June, 1782.

BLIND, an epithet applied to an animal deprived of the use of eyes; or one from whom light, colours, and all the glorious objects of the visible creation, are intercepted by some natural or accidental cause.

BLINDNESS; a privation of the sense of sight. The ordinary causes of blindness are, some external violence, vicious conformation, growth of a cataract, gutta serena, small-pox, &c; or a decay of the optic nerve; an instance of which we have in the Academy of Sciences, where, on opening the eye of a person long blind, it was found that the optic nerve was extremely shrunk and decayed, and without any medulla in it. The more extraordinary causes of blindness are malignant stenches, poisonous juices dropped into the eye, baneful vermin, long confinement in the dark, &c.

We find various compensations for blindness, or substitutes for the use of eyes, in the wonderful sagacity of many blind persons, related by Zaphnius in his *Oculus Artificialis*, and others. In some the defect has been supplied by a most excellent gift of memory; others by a delicate nose or the sense of smelling; others by a very nice ear; and others again by an exquisite touch, or sense of feeling, which they have possessed in great perfection.

Some have been able to perform many sorts of curious works in the neatest and most dexterous manner. Aldrovandus speaks of a sculptor, who had become blind at 20 years of age, and yet 10 years afterwards he made a perfect marble statue of Cosmo II de Medicis, and another of clay like pope Urban VIII. Bartholin speaks of a blind sculptor in Denmark, who, by mere touch, distinguished perfectly well every kind of wood, and even colours; and father Grimaldi relates an instance of the same kind; besides the blind organist, lately living in Paris, who it was said did the same thing. What seems more extraordinary still, we are told by authors of good report, of a blind guide, who used to conduct the merchants through the sands and deserts of Arabia; and a not less marvellous instance is now existing in this country, in one John Metcalf, near Manchester, who became quite blind at a very early age; and yet passed many years of his life as a waggoner, and occasionally, as a guide in different roads during the night, or when the paths were covered with snow; and, what is stranger still, his present occupation is that of surveyor and projector of highways in difficult and mountainous parts, particularly about Buxton, and the Peak in Derbyshire.

There are also many instances of blind men who have been highly distinguished for their mental and literary talents, not to speak of the poets Homer, Milton, Ossian, &c; of these we have a remarkable instance in the late Dr. Sanderson, professor of mathematics in the university of Cambridge, and in Dr. Henry Moyes, public lecturer in philosophy, who both of them lost their sight by the small-pox at an age before they had any recollection; these men were well skilled in all branches of the mathematics, philosophy, optics, &c, which they taught with the greatest reputation; besides the monument of fame which the former has left behind him in his mathematical and philosophical works. Another instance of these very extraordinary characters is likewise evinced in the present day, in Mr. John Gough of Middlesbrough, near Kendal, who, though blind from his infancy, has nevertheless acquired not only a very extensive knowledge in almost all the

branches of the mathematics, but also in botany and chemistry.

The effects of a sudden recovery of sight in such as have been born blind, are also very remarkable. Devoid of the experience of distance and figure arising from sight, they are liable to the greatest mistakes in this respect; so much that it has been said they could not distinguish by the mere sight between a cube and a globe, without first touching them. Mr. Boyle mentions a gentleman that was blind, who having been restored to sight at 18 years of age, was nearly distracted with joy. See Boyle's works abridg'd, vol. 1, p. 4. See also a remarkable case of this kind in the Tatler, No. 55, vol. 1. And the gentleman couched by Mr. Chесelden had no ideas of colour, shape, or distance: though he knew the colours asunder in a good light during his blind state, yet when he saw them after he had been couched, the faint ideas he had of them before, were not sufficient for discriminating them afterwards. As to distance, his ideas were so deficient, that he thought all the objects he saw touched his eyes, as what he felt did his skin; and it was a considerable time before he could remember which was the dog and which the cat, though often informed, without feeling them.

BLINDS, or **BLINDES**, in Fortification, a kind of defence usually made of oziors or branches interwoven, and laid across between two rows of stakes, about a man's height, and 4 or 5 feet asunder. They are used particularly at the heads of trenches, when these are extended in front towards the glacis, serving to defend the workmen, and prevent the enemy from overlooking them.

BLOCKADE, is the blocking up of a place by posting troops in all the avenues and roads leading to it, to prevent farther supplies of men and provisions to the besieged, and thus starving them out, without forming any regular siege or attacks.

BLONDEL (FRANCIS), a celebrated French mathematician and military engineer, was born at Ribemond in Picardy in 1617. While he was yet but young, he was chosen Regius Professor of Mathematics and Architecture at Paris. Not long after he was appointed governor to Lewis-Henry de Lomenix, Count de Brienne, whom he accompanied in his travels from 1652 to 1655, of which he published an account. He enjoyed many honourable employments, both in the navy and army; and was intrusted with the management of several negotiations with foreign princes. He arrived at the dignity of marshal de camp, and counsellor of state, and had the honour to be appointed mathematical preceptor to the dauphin. He was a member of the Royal Academy of Sciences, director of the Academy of Architecture, and lecturer to the Royal College, in all which he supported his character with dignity and applause. Blondel was no less versed in the knowledge of the belles lettres than in the mathematical sciences, as appears by the comparison he published between Pindar and Horace. He died at Paris the 22d of February 1686, in the 69th year of his age. His chief mathematical works were,

1. *Cours d'Architecture*. Paris, 1675, in folio.
2. *Resolution des Quatre Principaux Problèmes d'Architecture*. Paris, 1676, in folio.
3. *Histoire du Calendrier Romain*. Paris, 1682, in 4to.
4. *Cours de Mathématiques*. Paris, 1683, in 4to.
5. *L'Art de jeter des Bombes*. La Haye, 1685, in 4to. Besides A New Method of fortifying Places, and other works.

Blondel had also many ingenious pieces inserted in the Memoirs of the French Academy of Sciences, particularly in the year 1666.

BLOW, in a general sense, denotes a stroke given either with the hand, a weapon, or an instrument. The effect of a blow is estimated like the force of percussion, and expressed also by the velocity of the body multiplied by its weight.

BLOWING of a *Fire-arm*, is when the vent or touch-hole is run or gullied, and becomes wide, so that the powder will flame out.

BLUE, one of the seven primitive colours of the rays of light, into which they are divided when refracted through a glass prism. See Newton's Optics, &c. See also CHROMATICS.

BLUENESS, that quality of a body, as to colour, from which it is called blue; depending on such a size and texture of the parts that compose the surface of a body, as disposes them to reflect only the blue or azure rays of light to the eye.

The blueness of the sky is thus accounted for by De la Hire, after Da Vinci; viz, that a black body viewed through a thin white one, gives the sensation of blue, like the immense-expansive viewed through the air illuminated and whitened by the sun. For the same reason he says it is, that soot mixed with white, makes a blue; for that white bodies, being always somewhat transparent, when mixing with a black behind, give the perception of blue. From the same principle too he accounts for the blueness of the veins on the surface of the skin, though the blood they are filled with be a deep red.

In the same manner was the blue colour of the sky accounted for by many other of the earlier writers, as Fromondus, Funcieus, Otto Guericke, and many others, with several of the more modern writers, Wolfius, Muschenbroek, &c. But in the explication of this phenomenon by Newton, he observes, that all the vapours, when they begin to condense and coalesce into natural particles, become first of such a magnitude as to reflect the azure rays, before they can constitute clouds of any other colour. This being therefore the first colour they begin to reflect, must be that of the finest and most transparent skies, in which the vapours are not yet arrived at a grossness sufficient to reflect other colours.

Bouguer however ascribes this blueness of the sky to the constitution of the air itself, being of such a nature that these fainter-coloured rays are incapable of making their way through any considerable tract of it. And as to the blue shadows which were first observed by Buffon in the year 1742, he accounts for them by the aerial colour of the atmosphere, which enlightens these shadows, and in which the blue rays prevail; while the red rays are not reflected so soon, but pass on to the remoter regions of the atmosphere. And the Abbé Mazeau accounts for the phenomenon of blue shadows by the diminution of light; observing that, of two shadows which were cast upon a white wall from an opaque body, illuminated by the moon and by a candle at the same time, that from the candle was somewhat red, while the other from the moon was blue. See Newton's Optics, pa. 228; Bouguer *Traité d'Optique* pa. 368; Edinb. Ess. vol. 2, pa. 75; or Priestley's Hist. of Vision &c, pa. 436.

BLUNDERBUSS, in the Military Art, a short kind of fire-arm, with a large bore, contrived to carry a number of pistol or musket bullets at once. The blunderbuss is proper

to do execution in a crowd, or to make good any narrow passage.

BLUNDEVILLE (THOMAS), of Newton Flotman, a writer on navigation near the end of the 16th century. In his Briefe Description of Universal Mappes and Cardes, first printed in 1589, he gives an account of Gerard Mercator's universal map, observing that Bernard Putean of Bruges had published in 1579, one altogether like it. And though Blundeville is so particular, as to set down numbers expressing the distances between each parallel of latitude in those maps, yet he seems to slight them, by saying, that no better rules than those given by Ptolemy can be devised: but, in the after editions of his book, Blundeville omitted the commendation he had given of Ptolemy's method of delineating an universal map. But Blundeville's chief work seems to be his Exercises, written in 1593, the 4th edit. in 1613, 4to, 800 pages, containing treatises of Arithmetic; tables of Sines, Tangents, and Secants; Cosmographic; Description and Use of the Globes, Mappes, Cardes, Astrolabe, Navigation, &c.

BOB of a Pendulum, the same as the ball or weight; which see.

BODY, in Geometry, is a figure conceived to be extended in all directions, or what is usually said to consist of length, breadth, and thickness; being otherwise called a Solid. A body is conceived to be formed or generated by the motion of a surface; in the same manner as a surface is by the motion of a line, and a line by the motion of a point.—Similar bodies, or solids, are in proportion to each other, as the cubes of their like sides, or linear dimensions.

Body, in Physics, or Natural Philosophy, is a solid, extended, palpable substance; of itself merely passive, or rather being tenacious either of motion or rest, but capable of any sort of motion or figure.

Body is composed, according to the Peripatetics, of matter, form, and privation; according to the Epicureans and Corpuscularians, of an assemblage of hooked, heavy atoms; according to the Cartesians, of a certain extension; and according to the Newtonians, of a system or association of solid, massy, hard, impenetrable, moveable particles, ranged or disposed in a certain manner; from which arise bodies of various kinds, and distinguished by particular names: these elementary or component particles of bodies, they assert, must be perfectly hard, so as never to wear or break in pieces; which, Newton observes, is necessary, in order to the world's persisting in the same state, and bodies continuing of the same nature and texture in several ages.

Body of a piece of Ordnance, the part contained between the centre of the trunnions and the cascabel. This should always be more fortified or stronger than the rest, to sustain the first or greatest effort of the powder. See CANNON.

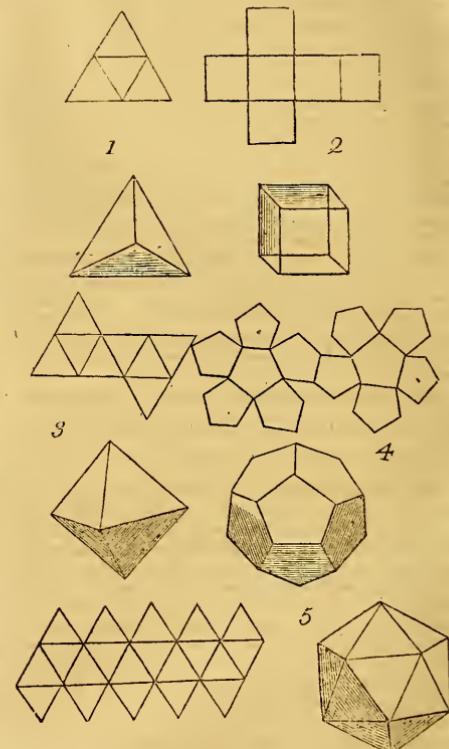

Body of the Place, in Fortification, denotes either the buildings inclosed, or more generally the inclosure itself. Thus to construct the body of the place, is to fortify or inclose the place with bastions and curtains.

Body of a Pump, the thickest part of the barrel or pipe of a pump, within which the piston moves.

Bodies, Regular or Platonic, are those which have all their sides, angles, and planes, similar and equal. Of these there are only 5; viz., the Tetraedron, contained by 4 equilateral triangles; the Hexaedron or cube, by 6 squares; the Octaedron, by 8 triangles; the Dodecaedron, by 12 pentagons; and the Icosaedron, by 20 triangles.

To form the five Regular Bodies.

Let the annexed figures be exactly drawn on pasteboard, or stiff paper, and cut out by the extreme or bounding lines: then cut the others, or internal lines, only half through, so that the parts may be turned up by them, and then glued or otherwise fastened together with paste, sealing-wax, &c; so shall they form the respective body marked with the corresponding number; viz., $\text{No}^{\circ} 1$ the tetraedron, $\text{No}^{\circ} 2$ the hexaedron or cube, $\text{No}^{\circ} 3$ the octaedron, $\text{No}^{\circ} 4$ the dodecaedron, and $\text{No}^{\circ} 5$ the icosaedron.

To find the Superficies or Solidity of the Regular Bodies.

1. Multiply the proper tabular area (taken from the following table) by the square of the linear edge of the solid, for the superficies.

2. Multiply the tabular solidity by the cube of the linear edge, for the solid content.

Table of the Surfaces and Solidities of the five Regular Bodies, the linear edge being 1.

No. of Faces	Names	Surfaces.	Solidities
4	Tetraedron	1.73205	0.11785
6	Hexaedron	6.00000	1.00000
8	Octaedron	3.46410	0.47140
12	Dodecaedron	20.64573	7.66312
20	Icosaedron	8.66025	2.18169

For more particular properties, see each respective word. See also my large Mensuration, pa. 185, edit. 4.

These bodies were called Platonic, because they were said to have been invented, or first treated of, by Plato, who conceived certain mysteries annexed to them.

BODIES, Descent of. See ACCELERATION.

BOETHIUS, or BOETIUS, (A. M. T. S.), a Roman philosopher and mathematician, was descended of a patrician family, and born at Padua in the 5th century. He studied at Athens, where he adopted the opinions of Aristotle; and, returning to Rome, was raised to the rank of senator and patrician, and even to the consulate, in 487. On the entry of Theodoric, king of the Goths into Rome, 500, Boethius pronounced his panegyric, in the name of the senate. He was consul in 510 and 511; but, in 523, having remonstrated against the violence of Theodoric, he was accused to that prince of having conspired with the emperor Justin against the Goths; and, being seized with his father-in-law Symeuchus, he was conducted to Padua, and there beheaded by order of Theodoric, in 524, after 6 months' imprisonment.—Besides some books on mystical divinity, Boethius wrote 5 books on the Consolation of Philosophy, said to have been composed to soften the rigour of his confinement; a work which has been translated into most other languages, particularly into Anglo-Saxon, by the illustrious Alfred. It seems that in his time they had the use of the Arabian arithmetic, with their ten numeral characters, which he employed, and from which our present numerals have been derived by several successive variations.

BOFFRAND (GERMAIN), a celebrated French architect and engineer, was born at Nantes in Bretagne, in 1667. He was brought up under Harduin Mansarad, who trusted him with conducting his greatest works. Boffrand was admitted into the French Academy of Architecture in 1709. Many German princes chose him for their architect, and raised considerable edifices on his plans. His manner of building approached that of Palladio; and there was much of grandeur in all his designs. As engineer and inspector-general of bridges and highways, he directed and constructed a number of canals, sluices, bridges, and other mechanical works. He published a curious and useful book, containing the general principles of his art; with an account of the plans, profiles, and elevations of the principal works which he executed in France and other countries. Boffrand died at Paris in 1755, dean of the Academy of Architecture, first engineer and inspector-general of the bridges and highways, and architect and administrator of the general hospital.

BOILING, or EBULLITION, the bubbling up of any fluid by the application of heat. This is, in general, occasioned by the discharge of an elastic vapour through the fluid, which is then said to boil; and the same appearance is observed, whether it be that of common air, fixed air, or steam, &c. It is proved by Dr. Hamilton of Dublin, in his Essay on the ascent of vapour, that the boiling of water is occasioned by the lowermost particles of it being heated and rarefied into vapour, or steam; in consequence of this diminution of their specific gravity, they ascend through the surrounding heavier fluid with great velocity, agitating and throwing up the body of water in their ascent, and giving it the tumultuous motion called boiling.

That this is occasioned by elastic steam, and not by particles of fire or air, as some have imagined, is easily proved by the following simple experiment: Take a common

drinking-glass filled with hot water, and invert it into a vessel of the same; then, as soon as the water in the vessel begins to boil, large bubbles will be seen to ascend in the glass, by which the water in it will be displaced, and there will soon be a continued bubbling from under its edge: but if the glass be then drawn up, so that its mouth may just touch the water, and a cloth wetted in cold water be applied to the outside, the elastic steam within it will be instantly condensed, on which the water will ascend so as nearly to fill it again. Some small parts of air &c, that may happen to be lodged in the fluid, may also perhaps be expelled, as well as the rarefied steam. And this is particularly recommended as a method of purifying quicksilver, for more accurately making barometers and thermometers. If a vessel containing water be placed over a steady fire, the water will grow continually hotter, till it reaches the limit of boiling; after which, the regular accessions of heat are wholly spent in converting it into steam, or the steam carries off the heat as fast as it is generated by the fire. The water therefore remains at the same degree of temperature, however fiercely it may boil; the only difference is, that with strong fire it sooner boils, and more quickly evaporates. Hence the reason why a vessel full of water, and plunged into the centre of a larger one, which is likewise filled with that fluid, barely acquires the boiling heat, but will never actually boil.

We commonly annex the idea of a certain very great degree of heat to the boiling of liquids, though often without reason; for different liquids boil with different degrees of heat; and any one given liquid also, under different pressures of the atmosphere. Thus, a vessel of tar being set over the fire till it boils, it is said a person may then put his hand into it without injury: and by putting water under the receiver of an air-pump, and applying the flame of a candle or lamp under it, it will be found, by gradually exhausting the receiver, that the water is made to boil with less and less degrees of heat: and without applying any heat at all, the water, or even the moisture about the bottom or edges of the receiver, will rise in an elastic vapour up into it, when the exhaustion is nearly completed.

Spirit of wine boils still sooner in vacuo than water. And Dr. Freind gives a table of the different times required to make several fluids boil by the same heat. See also Philos. Trans. No 122.

Every particular liquid has a fixed point of the thermometer, at which boiling takes place, and this is called the boiling point of the liquid. Thus, water begins to boil when heated to 212 degrees of Fahrenheit's scale. A strong heat makes it boil more rapidly, but does not increase its temperature: a fact which was first observed by Dr. Hooke. The annexed table

	Bodies.	Boiling point.
Æther	- - -	98
Ammonia	- - -	140
Alcohol	- - -	176
Water	- - -	212
Muriat of lime	- - -	230
Nitric acid	- - -	248
Sulphuric acid	- - -	500
Phosphorus	- - -	554
Oil of turpentine	- - -	560
Sulphur	- - -	570
Linseed oil	- - -	600
Mercury	- - -	660
		145° lower than in open

air, under a pressure of 30 inches of mercury: therefore water would boil in vacuo at 67° and alcohol at 34° . In Papin's digester, the temperature of water may be raised to 300 or 400 degrees, without ebullition; but the moment that the pressure is removed, the boiling commences with the greatest violence.

The mixture of various salts with water affects its boiling point considerably; as appears from Mr. Achard's experiments recorded in the Berlin Memoirs for 1785. He found that a saturated solution of muriat of soda raised the boiling point $10^{\circ}35$ degrees; one of muriat of ammonia raised it $9^{\circ}79$ degrees; one of carbonat of potass raised it $11^{\circ}2$ degrees; while a small quantity of borax lowered it $1^{\circ}35$ degrees; ditto of sulphat of magnesia lowered it $2^{\circ}47$ degrees; and sulphat of lime in any proportion lowered it $2^{\circ}02$ degrees.

BOMB, in Artillery, a shell or hollow ball of cast-iron, having a large vent, by which it is filled with gun-powder, and which is fitted with a fuze or hollow plug to give fire by, when thrown out of a mortar, &c. About the time when the shell arrives at the intended place, the composition in the pipe of the fuze sets fire to the powder in the shell, which blows it in pieces, to the great annoyance of the enemy, by killing the people, or firing the houses, &c. They are now commonly called Shells simply, in the English artillery.

These shells, or bombs, are of various sizes, from that of 17 or 18 inches diameter downwards. But these very large ones are not used by the English, that of 13 inches diameter being the greatest size now employed by them; the weight, dimensions, and other circumstances of the 13-inch shells, and of those downwards, are as in the following table.

Diameter of the Shell.	Weight of the Shell.	Powder to fill them.	Powder to burst them into most pieces.
13 inch	lbs. 195	lb. oz. 9 4½	lb. oz. 7 8
10	89	4 14½	3 4
8	46	2 3½	2 0
5½ Royal	14½	1 1½	0 14
4½ Cohorn	7½	0 8	0 7

Mr. Muller gives the following proportion for all shells. Dividing the diameter of the mortar into 30 equal parts, then the other dimensions, in 30ths of that diameter, will be thus:

Diameter of the bore, or mortar	-	-	30
Diameter of the shell	-	-	$29\frac{1}{2}$
Diameter of the hollow sphere	-	-	21
Thickness of metal at the fuze hole	-	-	$3\frac{1}{2}$
Thickness at the opposite part	-	-	5
Diameter of the fuze hole	-	-	4
Weight of shell empty	-	-	$\frac{10}{21}d$
Weight of powder to fill it	-	-	$\frac{2}{21}d$

where d denotes the cube of the diameter of the bore in inches.—But shells have also lately been made of the same thickness of metal throughout.

In general the windage, or difference between the diameter of the shell and mortar, is $\frac{1}{60}$ of the latter; also the diameter of the hollow part of the shell is $\frac{7}{8}$ of the same.

Bombs are thrown out of mortars, or howitzers; but they may also be thrown out of cannon; and a very small sort are thrown by the hand, which are called granados: and the Venetians at the siege of Candia, when the Turks had possessed themselves of the ditch, used large bombs

without any piece of ordnance, barely rolling them down upon the enemy along a plank set aslope, with ledges on the sides to keep the bomb directly forward.

Mr. Blondel, in his *Art de Jetter des Bombes*, says the first bombs were those thrown into the city of Watchtendonch in Guelderland, in 1588; and they are described by our countryman Lucar, in his book on Artillery published this same year 1588; though it is pretended by others that they were practised near a century before, namely at the siege of Naples in 1495. They only came into common use, however, in 1634, and then only in the Dutch and Spanish armies. It is said that one Malthus, an English engineer, was sent from Holland by Lewis the 14th, who used them for him with much success, particularly at the siege of Couloue in 1642.

The art of throwing bombs, or shells, constitutes one of the chief branches of Gunnery, founded on the theory of projectiles, and the quantities and laws of the force of gunpowder. And the principal writers on this art are Mess. Blondel, Guisnée, De Ressons, De La Hire, &c.

BOMB-CHEST, is a kind of chest usually filled with bombs, and sometimes only with gunpowder, placed under ground, to be blown up into the air with those who stand upon it; being set on fire by means of a saucisse fastened at one end. But they are now much out of use.

BOMBARD, an ancient piece of ordnance, now out of use. It was very short and thick, with a large mouth; some of which threw balls of 300 pounds weight, requiring the use of cranes to load them. The Bombard is by some called *basilisk*, and by the Dutch *donderbus*.

To BOMBARD, is to attack by throwing of bombs, or shells.

BOMBARDIER, a person employed in throwing bombs or shells. He adjusts the fuze, and loads and fires the mortar.

BOND (HENRY), was an intelligent mathematician, and a teacher of navigation at Ratcliff, near London, in the early part of the 17th century. In the course of his nautical concerns he interested himself much about the magnetic needle, its variation and inclination. The variation of the magnetic needle was first observed by John Moir, then by Edm. Gunter, next by Hen. Gallibrand, and then by our author Bond. In the year 1657 there was no variation at London: before that time it had been eastwards, as observed by several of those persons, but gradually decreasing, or the needle moving westwards, till it pointed due north in that year 1657; ever since it has been travelling westwards, but at unequal rates, till now, in 1812, it has arrived at above 24° west variation, and appears to be nearly stationary, after which it will probably return eastward again; according to which rate of motion, the magnetic needle, or pole, appears to perform an entire circular revolution in about 620 years. Besides the changeable variation east and west, the needle was also found to have a changeable inclination, or dip below the horizon; and on this last change it was that Mr. Bond founded his method of finding the longitude; which however has failed, as might be expected. On this method he published a book, called *The Longitude* found, printed at London 1676, in 4to. He here states, as his prediction, after many boasting and empirical pretensions, what would be the latitude, and longitude, and the inclination of the needle, in many of the most noted places on the earth, in the year 1676; also another table of the latitude of the magnetic pole, answering to every 5 minutes in the inclination of the needle. He also had inserted in the Philos.

Trans. No. 40, of the year 1668, or pa. 282, vol. 1, of my Abridgment, a table of the needle's variation at London, for every year from 1668 to 1716; when he states it at $9^{\circ} 17 \frac{1}{2}'$.

Dr. Birch states that Sir Charles Cavendish, brother to William, marquis, and afterwards duke of Newcastle, in an original letter of his from Antwerp, Nov. 13, 1648, to Mr. John Pell, then professor of mathematics at Breda, mentions Mr. Bond as an old mathematician at London, a humble man, who speaks, says he, very meanly of himself, and " yet he found an easy and short demonstration of that proposition concerning spherical triangles, which Mr. Oughtred demonstrated first, who told me, Mr. Bond's demonstration was shorter." Sir Charles adds, that Mr. Bond was in hopes of finding the longitude by the load-stone; and his treatise on that subject, entitled "The Longitude found," was printed at London 1676, in 4to.

Bond's scheme for the longitude was soon opposed, a book being published at London in 1678, called "The Longitude not found," written by one Beckborrow. And indeed as Bond's hypothesis did not in anywise answer its author's sanguine expectations, Dr. Halley also undertook this affair; and from a multitude of observations concluded, that the magnetic needle was influenced by four poles. His speculations on this subject are in the Philos. Trans. No. 148 and 195. But this wonderful phenomenon seems to have hitherto eluded all researches. However, Dr. Halley, in 1700, published a general map, on which were delineated curve lines, showing the paths where the magnetic needle had the same variation. The positions of these curves will indeed continually suffer alterations, requiring to be corrected from time to time, as they have since been for the years 1744 and 1756, by two ingenious persons, William Mountaine and James Dodson; the latter of whom died not long after he had been chosen, for his merit, mathematical master at Christ's Hospital, in London.

RONES, Napier's. See NAPIER.

BONING, in Surveying and Levelling, &c., is the placing three or more rods or poles, all of the same length, in or upon the ground, in such a manner, that the tops of them be all in one continued straight line, whether it be horizontal or inclined, so that the eye can look along the tops of them all, from one end of the line to the other.

BONNET, in Fortification, a small work of two faces, having only a parapet, with two rows of palisadoes at about 10 or 12 feet distance. It is commonly placed before the salient angle of the counterscarp, and having a communication with the covered way, by means of a trench cut through the glacis, and palisadoes on each side.

BONNET *d'Prêtre*, or *Priest's Cap*, is an outwork, having three salient angles at the head, besides two inwards. It differs from the double tenaille only in this, that its sides, instead of being parallel, become narrower, or closer, at the gorge, and opening at the front; from whence it is called Queue d'aronde, or swallow's tail.

BOOTES, a constellation of the northern hemisphere, and one of the 48 old ones; having 23 stars in Ptolemy's catalogue, 28 in Tycho's, 34 in Bayer's, 52 in Hevelius's, and 54 in Flamsteed's; of which one, in the skirt of the coat, is of the first magnitude, and called Arcturus.

BOOTES is represented as a man in the posture of walking; his right hand grasping a club, and his left extended upwards, and holding the cord of the two dogs which seem barking at the Great Bear.

This constellation is called by various other names; as VOL. I.

Arcas, Arctophylax, Arcturus-Minor, Bulbulcus, Bubulus, Canis-Latrans, Clamator, Icarus, Lycœon, Philometes, Plaustri-Custos, Plorans, Thengnis, and Vociferator; by Hesychius it is called Orion, and by the Arabs, Aramech, or Archamech. Schiller, instead of Bootes, makes the figure of St. Sylvester; Schickhard, that of Nimrod; and Weigelius, the three Swedish crowns. See Wolf. Lex Math. p. 266.

BORDA (CHARLES), a celebrated French mathematician and philosopher, died in 1799, in the 64th year of his age; in whom the National Institute, and the Parisian Board of Longitude, lost one of their most learned and active members. Borda very early gave proofs of his eminent mathematical talents; as appears by his many excellent tracts inserted in the Memoirs of the Royal Academy of Sciences, on a variety of abstruse subjects; on hydraulics, on the resistance of fluids, on water-wheels, on pumps, on the projection of military shells, and their resistance by the air, &c.

In 1771 and 1772, by order of the king, he accompanied La Crenne and Pingré, on a literary voyage to various coasts of Europe, Africa, and America, for improving the science of geography, and for trying several new nautical instruments, time-pieces, and methods of finding the longitude. The three travellers afterwards published conjointly, in 2 vols 4to, 1778, an account of the fruits of their numerous researches; in which Borda's share was certainly not the smallest. The results of this expedition are also recorded in the Memoirs of the Academy for the year 1773.

In the year 1787, he published his much-esteemed Description and Use of the Circle of Reflection; in which he revised and recommended the use of the specular circles, which had been proposed in 1756 by Tobias Mayer. Borda was the founder of the schools of naval architecture in France: he first conceived the project, and formed the plan of instruction, with the regulations for those seminaries. By his exertions too, a uniformity in the building of the ships was introduced, according to the principles of Euler, by which improvement, an equality of sailing was effected in all the ships of the royal navy. Hence, the form of the French ships, being constructed on mathematical principles, is clearly preferable to that of the ships of the other naval powers; being the most advantageous, and the best adapted for fast sailing, and for manœuvring.

Borda also brought into use Mayer's old method of measuring terrestrial angles, applied it to astronomical observations, and, for that purpose, invented a new construction of circles, with double moveable telescopes, which have been used in the new measurement of degrees in France. He was also the inventor of the ingenious mensuration rod, with which the new station-lines were measured; and he had the chief share in the reform of weights and measures; of which he was so zealous a promoter, that he printed, at his own expense, Tables of Sines, &c., on the decimal system. In 1792 he determined, with an accuracy perhaps never before attained, the length of the pendulum vibrating seconds at Paris. In 1797, we find his name in the list of candidates for the office of Director of the French Republic.

BORE, of a gun, or other piece of ordnance, is the chase, cylinder, or hollow part of the piece.

BOREAL SIGNS, are the first six signs of the Zodiac, or those on the northern side of the equinoctial; viz, the signs ♀ aries, ♂ taurus, ♊ gemini, ♂ cancer, ♋ leo, ♌ virgo.

BOREALIS, AURORA. See **AURORA Borealis.**

BORELLI (JOHN ALPHONSO), a celebrated philosopher and mathematician, born at Naples the 28th of Jan. 1608. He was professor of philosophy and mathematics in some of the most celebrated universities of Italy, particularly at Florence and Pisa, where he became highly in favour with the princes of the house of Medicis. But having been concerned in the revolt of Messina, he was obliged to retire to Rome, where he spent the remainder of his life under the protection of Christina, queen of Sweden, who honoured him with her friendship, and by her liberality towards him softened the rigour of his hard fortune. He continued two years in the convent of the regular clergy of St. Pantaleon, called the Pious Schools, where he instructed the youth in the mathematical sciences. And this study he prosecuted with great diligence for many years afterward, as appears by his correspondence with several ingenious mathematicians of his time, and the frequent mention that has been made of him by others, who have endeavoured to do justice to his memory. He wrote a letter to Mr. John Collins, in which he discovers his great desire and endeavours to promote the improvement of those sciences: he also speaks of his correspondence with, and great affection for, Mr. Henry Oldenburg, Secretary of the Royal Society; of Dr. Wallis; of the then late learned Mr. Boyle, and laimited the loss sustained by his death to the commonwealth of learning. Mr. Baxter, in his Enquiry into the Nature of the Human Soul, makes frequent use of our author's book *De Motu Animalium*, and tells us, that he was the first who discovered that the force exerted within the body prodigiously exceeds the weight to be moved without, or that nature employs an immense power to move a small weight. He acknowledges, however, that Dr. James Keil had shown that Borelli was mistaken in his calculation of the force of the muscle of the heart; but that he nevertheless ranks him with the most authentic writers, and says he is seldom mistaken: and, having remarked, that it is so far from being true that great things are brought about by small powers, that, on the contrary, a stupendous power is manifest in the most ordinary operations of nature, he observes that the ingenious Borelli first observed this in animal motion; and that Dr. Stephen Hales, by a course of experiments in his Vegetable Statics, had shown the same in the force of the ascending sap in vegetables. And this circumstance, that nature employs a very great power, or force, in the animal frame, to move a small weight, we may here observe, is owing to the levers in the animal frame being all necessarily of the third kind, the power acting very near the centre of motion, and the weight at a comparatively great distance from it.

After a course of unceasing labours, Borelli died at Pantaleon of a pleurisy, the 31st of December 1679, at 72 years of age.

Beside several books on physical subjects, Borelli published the following mathematical ones: viz,

1. *Apollonii Pergei Conicorum Lib. 5, 6, and 7.* Floren. 1661, fol.
2. *Theoræ Medicorum Planetarum ex causis physicis deductæ.* Flor. 1666, 4to.
3. *De Vi Percussionis.* Bologna, 1667, 4to.—This piece was reprinted, with his celebrated treatise *De Motu Animalium*, and that other *De Motionibus Naturalibus*, in 1686.
4. *Euclides Restitutus, &c.* Pisa, 1668, 4to.

5. *Osservazione intorno alla vista inequali degli Occhi.*—This piece was inserted in the Journal of Rome, for the year 1669.

6. *De Motionibus Naturalibus de Gravitate pendentibus.* Regio Julio, 1670, 4to.

7. *Meteorologia Aetnea, &c.* Regio Julio, 1670, 4to.

8. *Osservazione dell' Ecclissi Lunare,* 11 Gennaro 1675.—Inserted in the Journal of Rome 1675, p. 34.

9. *Elementa Conica Apollonii Pergei, et Archimedis Opera, nova et breviori methodo demonstrata.*—Printed at Rome in 1679, in 12mo, at the end of the 3d edition of his *Euclides Restitutus.*

10. *De Motu Animalium.* Pars prima in 1680, and Pars altera in 1681, 4to.—These were reprinted at Leyden 1685, revised and purged from many errors; with the addition of John Bernoulli's Mathematical Meditations concerning the Motion of the Muscles.

11. At Leyden, 1686, in 4to, a more correct and accurate edition, revised by J. Broen, m. d. of Leyden, of his two pieces, *De Vi Percussionis*, et *De Motionibus de Gravitate pendentibus.*

BORELLI (PETER), who flourished about the middle of the 16th century, appears to have been a native of Middleburg, capital of the island of Walcheren and all Zealand; and was counsellor and physician in ordinary to his most Christian majesty. He wrote two treatises on the telescope and microscope, printed at the Hague, in 1655 and 1656. The former is very full and particular treatise on the history of the invention of those very useful instruments; which, by a train of strong evidence he ascribes to Zachariah Jansen, a spectacle-maker of Middleburg, in 1590. He gives a particular account of the pretensions that have been ascribed to all the other persons that have been named as the inventors; the whole forming a very interesting history of the invention. The chief body of evidence it seems he received from a Wm. Borelli, of the same city, some time ambassador in England; but whether any relation of Peter's does not appear.

The first volume consists of two parts: the former treating of the invention itself; and the latter of the fabric, construction, and uses of the instruments. The second volume contains the account and appearances of one hundred minute objects, as viewed by the microscope. The volumes are both neatly printed in 4to, by Adrian Vlaeq, at the Hague.

BOSCOVICH (ROGER JOSEPH), an eminent mathematician and philosopher, was born May 11th, 1711, at Ragusa. He studied Latin grammar in the schools which were taught by the Jesuits in his native city, until 1725, when, in consistence with a maxim of the Jesuits to send their most eminent pupils to Rome for the completion of their education, he was removed to that city. After this he soon acquired very great reputation for his eminent attainments in divinity and science: at three successive periods he became professor of mathematics and astronomy at Rome, at Pavia, and at Milan. When the order of Jesuits was suppressed he was invited to Paris, and received the place of director of the optical instruments of the marine. Previous to this however he had been employed, in conjunction with Mayer, in measuring a degree of the meridian in Italy, and correcting the maps of the Papal estate. He published, in 1755, an interesting account of the expedition in which these objects were effected. He had also been employed in adjusting a disagreeable affair between the republic of Lucca and the regency of Tuscany, and in a

similar business between the republic of Ragusa and the court of Great Britain, which brought him to London, where he soon became acquainted with the most eminent of the English philosophers. During his stay he was elected a fellow of the Royal Society, and he dedicated to that learned body his Poem on Eclipses, which contains a neat compendium of astronomy. He remained at Paris 10 years, where he was much respected; but, being a foreigner, his celebrity was envied: this, together with the irreligion which then prevailed among many of the French philosophers, was disagreeable to him, so that he obtained leave of absence to revisit his friends in Italy. The first place he resided at for any considerable length of time in Italy, was Bassano, where he published his *Opuscules*, in five volumes 4to, composed in Latin, Italian, and French; and containing a variety of elegant and ingenious disquisitions connected with astronomical and optical science. From Bassano our author went to Rome, and thence to Milan, where he took up his abode; being in the neighbourhood of his favourite observatory at Brera. Here he continued to enjoy the pleasures of study, and occasionally the society of many respected friends. His unwillingness to leave Italy, and at the same time a solicitude to avoid the charge of ingratitude from the French nation, occasioned him great perplexity of mind, which was followed by deep melancholy, a disordered imagination, and at length direct madness. During the heat of delirium, he frequently exclaimed that he would die poor and inglorious. He had indeed some short lucid moments, and once there were hopes of his recovery; but he soon relapsed, and an imposthume, breaking in his breast, put an end to his mortal life the 13th of Feb. 1787, in his 76th year. He was interred decently, but without pomp, in the parochial church of S. Maria Pedrone. "Such was the exit," says Fabroni, "of this sublime genius, whom Rome honoured as her master; whom all Italy regarded as her ornament; and to whom Greece would have erected a statue, had she for want of space been obliged even to throw down some of her heroes." The works of this memorable man are the following:—1. Elements of Mathematics, with a Treatise on Conic Sections. 2. His many Dissertations published during his professorship in the Roman College. 3. His Account of the Survey of the Pope's Estate. 4. A curious and elegant Poem on Solar and Lunar Eclipses. 5. The five volumes published at Bassano. 6. His Hydronomical Pieces. 7. A Theory of Natural Philosophy.

BOUGUER (PETER), a celebrated French mathematician, was born at Croisic, in Lower Bretagne, the 10th of February 1698. He was the son of John Bouguer, Professor Royal of Hydrography, a tolerably good mathematician, and author of A complete Treatise on Navigation. Young Bouguer was accustomed to learn mathematics from his father, from the time he was able to speak, and thus became a proficient in those sciences while he was yet a child. He was sent very early to the Jesuits' college at Vannes, where he had the honour to instruct his regent in the mathematics, at eleven years of age.

Two years after this he had a public contest with a professor of mathematics, on a proposition which the latter had advanced erroneously; and he triumphed over him; on which the professor, unable to bear the disgrace, left the country.

Two years after this, when young Bouguer had not yet

finished his studies, he lost his father; whom he was appointed to succeed in his office of hydrographer, after a public examination of his qualifications; being then only 15 years of age; an occupation which he discharged with great respect and dignity at that early age.

At the age of 28 in 1727 he obtained the prize proposed by the Academy of Sciences, for the best way of masting ships. This first success of Bouguer was soon after followed by two others of the same kind; he successively gained the prizes of 1729 and 1731; the former, for the best manner of observing at sea the height of the stars; and the latter, for the most advantageous way of observing the declination of the magnetic needle, or the variation of the compass.

In 1729, he gave an Optical Essay upon the Gradation of Light; a subject quite new, in which he examines the intensity of light, and determines its degrees of diminution in passing through different pellucid mediums, and particularly that of the sun in traversing the earth's atmosphere. Mairan gave an extract of this first essay in the Journal des Savans, in 1730.

During this year, 1730, he was removed from the port of Croisic to that of Hayre, which brought him into a nearer connection with the Academy of Sciences, in which he obtained, in 1731, the place of associate geometerian, vacant by the promotion of Maupertuis to that of pensioner; and in 1735 he was promoted to the office of pensioner-astronomer. The same year he was likewise sent on the commission to South America, along with Messieurs Godin, Condamine, and Jeussieu, to determine the measure of the degrees of the meridian, and the figure of the earth. In this painful and troublesome business, of 10 years' duration, chiefly among the lofty Cordelier mountains, our author determined many other new circumstances, besides the main object of the voyage; such as the expansion and contraction of metals and other substances, by the sudden and alternate changes of heat and cold among those mountains; observations on the refraction of the atmosphere from the tops of the same, with the singular phenomenon of the sudden increase of the refraction, when the star can be observed below the line of the level; the laws of density of the air at different heights, from observations made at different points of these enormous mountains; a determination that the mountains have an effect on a plumbum, though he did not assign the exact quantity of it; a method of estimating the errors committed by navigators in determining their course; a new construction of the log for measuring a ship's way; with several other useful improvements.

Other inventions of Bouguer, made upon different occasions, were as follow: The heliometer, being a telescope with two object glasses, affording a good method of measuring the diameters of the larger planets with ease and exactness: his researches on the figure in which two lines or two long ranges of parallel trees appear: his experiments on the famous reciprocity of the pendulum: and those upon the manner of measuring the force of light: &c, &c.

The close application which Bouguer made to study, undermined his health, and terminated his life the 15th of August 1758, at 60 years of age.—His chief works, that have been published, are,

1. The Figure of the Earth, determined by the observations made in South America; 1749, in 4to.

2. Treatise on Navigation and Pilotage; Paris, 1752,

in 4to. This work has been abridged by M. La Caille, in 1 volume, 8vo, 1768.

3. Treatise on Ships, their Construction and Motions; in 4to, 1756.

4. Optical Treatise on the Gradation of Light; first in 1729; then a new edition in 1760, in 4to.

His papers that were inserted in the Memoirs of the Academy, are very numerous and important: as, in the Memoirs for 1720, On the Comparison of the force of the solar and lunar light with that of candles.—1731, Observations on the curvilinear motion of bodies in mediums.—1732, On the new curves called the Lines of Pursuit.—1733, To determine the species of conoid, to be constructed on a given base which is exposed to the action of a fluid, so that the impulse may be the least possible.—Determination of the orbit of comets.—1734, Comparison of the two laws which the earth and the other planets must observe under the figure which gravity causes them to take.—On the curve lines proper to form the arches in domes.—1735, Observations on the equinoxes.—On the length of the pendulum.—1736, On the length of the pendulum in the torrid zone.—On the manner of determining the figure of the earth by the measure of the degrees of latitude and longitude.—1739, On the astronomical refractions in the torrid zone.—Observations on the lunar eclipse of the 8th of September 1737, made at Quito.—1744, Short account of the voyage to Peru, by the members of the Royal Academy of Sciences, to measure the degrees of the meridian near the equator, and from thence to determine the figure of the earth.—1745, Experiments made at Quito, and divers other places in the torrid zone, on the expansion and contraction of metals by heat and cold.—On the problem of the masting of ships.—1746, Treatise on ships, their structure and motions.—On the impulse of fluids upon the fore parts of pyramidoids having their base a trapezium.—Continuation of the short account given in 1744, of the voyage to Peru for measuring the earth.—1747, On a new construction of the log, and other instruments for measuring the run of a ship.—1748, On the diameters of the larger planets. The new instrument called a Heliometer, used for determining them; with observations of the sun.—Observation on the eclipse of the moon the 8th of August 1748.—1749, Second memoir on astronomical refractions, observed in the torrid zone, with remarks on the manner of constructing the tables of them.—Figure of the earth determined by MM. Bouguer and Condamine, with an abridgment of the expedition to Peru.—1750, Observation of the lunar eclipse of the 13th of December 1750.—1751, On the form of bodies most proper to be assumed for their revolution, when they are urged at one of their extremities, or any other point.—On the moon's parallax, with the estimation of the changes caused in the parallaxes by the figure of the earth.—Observation of the lunar eclipse, the 2d of December 1751.—1752, On the operations made by seamen, called Corrections.—1753, Observation of the passage of Mercury over the sun, the 6th of May 1753.—On the dilatations of the air in the atmosphere.—New treatise of navigation, containing the theory and practice of piloting, or working of ships.—1754, Operations, &c, for distinguishing, among the different determinations of the degree of the meridian near Paris, that which ought to be preferred.—On the direction which the string of a plummet takes.—Solution of the chief problems in the working of ships.—1755, On the ap-

parent magnitude of objects.—Second memoir on the chief problems in the working of ships.—1757, Account of the treatise on the working of ships.—On the means of measuring the light.—1758, His Eulogy.

In the volumes of the prizes given by the academy, are the following pieces, by Bouguer:

In vol. 1, on the masting of ships.—Vol. 2, On the method of exactly observing at sea the height of the stars; and the variation of the compass. Also on the cause of the inclination of the planets' orbits.

BOULTINE, in Architecture, a convex moulding, of a quarter of a circle, and placed next below the plinth in the Tuscan and Doric capital.

BOURNE (Wm.), was a useful and ingenious writer on navigation about the middle of the 16th century. In 1567 was published what he calls "Rules of Navigation," as appears from his Almanac, printed in 1571. And in 1577 was published his "Regiment for the Sea," designed as a supplement to Cortes, whom he often quotes. Besides many things common with others, Bourne gives a table of the places and declinations of 32 principal stars, by which to find the latitude and hour; as also a larger tide-table than that published by Leonard Digges, in 1556. He shows, by considering the irregularities in the moon's motion, the errors of the sailors in finding her age by the epact; as also in their determining the hour from observing on what point of the compass the sun and moon appeared. He advises, in sailing towards high latitudes, to keep the reckoning by the globe; as there the plane chart errs most. He despairs of our ever being able to find the longitude by any instrument, unless the variation of the compass should be caused by some such attractive point as Cortes had imagined. Though of this he doubts: and as he had shown how to find the variation of the compass at all times, he advises to keep an account of the observations, as useful to discover the place of a ship: which advice the famous Simon Stevin prosecuted at large, in a treatise published at Leyden in 1599, entitled "Portuum investigandorum Ratio Metaphrasto Hugone Grotio;" the substance of which was the same year printed at London, in English, by Edw. Wright, entitled "The Haven-finding Art."

But the most remarkable thing in this ancient tract is, the describing of the way by which our sailors estimated the rate a ship made in her course, by an instrument called the Log; an instrument so named from the wooden log that floats in the water, while the time is reckoned during which the line fastened to it is veering out. The origin of this device is not known; and it seems no further mention was made of it till 1607, in an East-India voyage, published by Purchas; but from that time its name occurs in other voyages, among his collections. And henceforward it was often noticed, by foreigners as well as our own authors; as by Gunter in 1623, Snellius in 1624, Metius in 1631, Oughtred in 1633, Herigone in 1634, Saltonstall in 1636, Norwood in 1637, Fournier in 1643; and indeed by most succeeding writers on navigation of every country. And it still continues to be in use as at first, though attempts have often been made to improve it, and other contrivances proposed to supply its place. Many of these have succeeded in quiet water, but proved useless in a troubled sea. See our article Log.

A following edition of this book was revised by the author; among the additions to which, he enlarges on the account of the log-line; and at the end subjoins a "Hy-

drographical Discourse touching the five several Passages into Cathay." Bourne published other tracts also; as, one entitled "Inventions or Devises;" where he describes a method, by wheel-work, of measuring the velocity of a ship at sea; an artifice which he attributes to one Humphrey Cole.

BOW, an offensive weapon made of wood, horn, steel, or other elastic matter, by which arrows are thrown with great force. This instrument was of very general use among the ancients, and is still found among all savage nations unacquainted with the use of fire-arms. There are two species of the Bow, the Long and the Cross Bow.

The *Long Bow* is simply a bow, or a rod, with a string fastened to each end of it, to the middle of which the end of an arrow being applied, and then drawn by the hand, on suddenly quitting the hold, the bow returns by means of its elasticity, and impels the arrow from the string with great violence. The old English archers were famous for the long bow, by means of which they gained many victories in France and other countries.

The *Cross Bow*, called also Arbalet or Arbalet, is a bow strung and set in a shaft of wood, and furnished with a trigger; serving to throw bullets, darts, and large arrows, &c. The ancients had large machines for throwing many arrows at once, called Arbalets, or Baliste.

The force of a bow may be calculated on this principle, that its spring, i. e. the power by which it restores itself to its natural position, is always proportional to the space or distance it is bent or removed from it.

Bow, a mathematical instrument formerly used at sea for taking the sun's altitude. It consisted of a large arch divided into 90 degrees, fixed on a staff, and furnished with three vanes, viz. a side vane, a sight vane, and another called the horizon vane.

Bow-Compass, an instrument for drawing arches of very large circles, for which the common compasses are too small. It consists of a beam of wood or brass, with three long screws that govern or bend a lath of wood or steel to any arch.

BOX AND NEEDLE, the small compass of a theodolite, circumferentor, or plain-table.

BOYAU, in Fortification, a ditch covered by a parapet, and serving as a communication between two trenches. It runs parallel to the works of the body of the place, and serves as a line of contravallation, both to hinder the salries of the besieged, and to secure the miners. When it is a particular cut running from the trenches, to cover some spot of ground, it is drawn so as not to be enfiladed or scoured by the enemy's shot.

BOYLE (ROBERT), one of the greatest philosophers, as well as best men, that any country has ever produced, was the 7th son and the 14th child of Richard earl of Cork, and was born at Lismore in the province of Munster in Ireland, the 25th of January, 1626-7; the very year of the death of the learned Lord Bacon, whose plans of experimental philosophy our author afterwards so ably seconded. While very young, he was instructed in his father's house to read and write, and to speak French and Latin. In 1635, when only 8 years old, he was sent over to England to be educated at Eton school. Here he soon discovered an extraordinary force of understanding, with a disposition to cultivate and improve it to the utmost.

After remaining at Eton between 3 and 4 years, his father sent our author and his brother Francis, in 1638, on their travels upon the continent. They passed through France to Geneva, where they settled for some time to pur-

sue their studies: here our author resumed his acquaintance with the elements of the mathematics, which he had commenced at Eton when 10 years old, on account of an illness which prevented his other usual studies.

In the autumn of 1641 he quitted Geneva, and travelled through Switzerland and Italy to Venice, whence he returned again to Florence, where he spent the winter, studying the Italian language and history, and also the works of the celebrated astronomer Galileo, who died in a village near this city during Mr. Boyle's residence here.

About the end of March 1642, he set out from Florence, visited Rome and other places in Italy, then returned to the south of France. At Marseilles, in May 1642, Mr. Boyle received letters from his father, which informed him that the rebellion had broken out in Ireland, and with what difficulty he had procured 250*l* then remitted to help him and his brother home. This remittance however never reached them, and they were obliged to return to Geneva with their governor Mr. Marcombe, who contrived on his own credit, and by selling some jewels, to raise money enough to bring them to England, where they arrived in 1644. On their arrival they found that their father was dead, and had left our author the manor of Stalbridge in England, with some other considerable estates in Ireland.

From this time Mr. Boyle's chief residence, for some years at least, was at his manor of Stalbridge, whence he made occasional excursions to Oxford, London, &c; applying himself with great industry to various kinds of studies, but especially to philosophy and chemistry; and seizing every opportunity of cultivating the acquaintance of the most learned men of his time. He was one of the members of that small but learned body of men, in 1645, who, when all academical studies were interrupted by the civil wars, secreted themselves; and held private meetings, first in London, afterwards at Oxford, to cultivate subjects of natural knowledge on that plan of experiment which Lord Bacon had delineated. They styled themselves then The Philosophic College; but after the restoration, when they were incorporated, and distinguished openly, they took the name of the Royal Society.

In the summer of 1654 he retired to settle at Oxford, the Philosophical Society being removed from London to that place, that he might enjoy the conversation of the other learned members, his friends, who had retired thither, such as Wilkins, Wallis, Ward, Willis, Wren, &c. It was during his residence here that he improved that admirable engine the air-pump; and by numerous experiments was enabled to discover several qualities of the air, so as to lay a foundation for a complete theory. He declared against the philosophy of Aristotle, as having in it more of words than things; promising much, but performing little; and giving the inventions of men for indubitable proofs, instead of building on observation and experiment. He was also so zealous for this true method of learning by experiment, and so careful about it, that though the Cartesian philosophy then made a great interest in the world, yet he could never be persuaded to read the works of Descartes, for fear he should be amused and led away by plausible accounts of things founded on conjecture, and merely hypothetical. But philosophy, and inquiries into nature, though they engaged his attention deeply, did not occupy him entirely; as he still continued to pursue critical and theological studies. He had offers of preferment to enter into holy orders, by the government, after the restoration. But he declined the offer, choosing rather to pursue his

studies as a layman, in such a manner as might be most effectual for the support of religion; and began to communicate to the world the fruits of these studies. These productions were very numerous and important, as well as various: the principal of which, as well as of some other memorable occurrences of his life, were nearly in the following order:

In 1660 came out, 1. New experiments, physico-mechanical, touching the spring of the air and its effects.—2. Seraphic love; or some motives and incentives to the love of God, pathetically discoursed of in a letter to a friend. A work which it has been said was owing to his courtship of a lady, the daughter of Cary earl of Monmouth; though our author was never married.—3. Certain physiological essays and other tracts, in 1661.—4. Sceptical chemist, 1662; reprinted about the year 1679, with the addition of divers experiments and notes on the producibleness of chemical principles.

In the year 1663, the Royal Society being incorporated by king Charles the 2d, Mr. Boyle was named one of the council; and as he might justly be reckoned among the founders of that learned body, so he continued one of the most useful and industrious of its members during the whole course of his life. His next publications were, 5. Considerations touching the usefulness of experimental natural philosophy, 1663.—6. Experiments and considerations upon colours; to which was added a letter, containing Observations on a diamond that shines in the dark, 1663. This treatise is full of curious and useful remarks on the hitherto unexplained doctrine of light and colours; in which he shows great judgment, accuracy, and penetration; and which may be said to have led the way for Newton, who made such brilliant discoveries in that branch of physics.—7. Considerations on the style of the holy Scriptures, 1663. This was an extract from a larger work, entitled An essay on Scripture; which was afterwards published by Sir Peter Pett, a friend of Mr. Boyle's.

In 1664 he was elected into the company of the royal miners; and was all this year occupied in prosecuting various good designs, which was probably the reason that he did not publish any works in this year. Soon after came out, 8. Occasional reflections upon several subjects, 1665. This piece exposed our author to the censure of the celebrated Dean Swift, who, to ridicule these discourses, wrote A Pious Meditation upon a Broomstick, in the Style of the honourable Mr. Boyle.—9. New experiments and observations upon cold, 1665.—10. Hydrostatical paradoxes made out by new experiments, for the most part physical and easy, 1666.—11. The origin of forms and qualities, according to the corpuscular philosophy, 1666.—Both in this and the former year, our author communicated to his friend Mr. Oldenburg, then secretary to the Royal Society, several curious and excellent short pieces of his own, on a great variety of subjects, and others transmitted to him by his learned friends, which are printed in the Philosophical Transactions.

In the year 1668 Mr. Boyle resolved to settle in London for life; and for that purpose he removed to the house of his sister, the Lady Ranelagh, in Pall-Mall. This removal was to the great benefit of the learned in general, and particularly of the Royal Society, to whom he gave great and continual assistance, as abundantly appears by the several pieces communicated to them from time to time, and printed in their Transactions. To avoid improper waste of time, he had set hours in the day appointed for receiv-

ing such persons as wanted to consult him, either for their own assistance, or to communicate new discoveries to him; and he besides kept up an extensive correspondence with the most learned men in Europe; so that it is wonderful how he could bring out so many new works as he did. His next publications were, 12. A continuation of new experiments touching the weight and spring of the air; to which is added, A discourse of the atmosphere of consistent bodies, 1669.—13. Tracts about the cosmical qualities of things; cosmical suspicions; the temperature of the subterraneous regions; the bottom of the sea; to which is prefixed an introduction to the history of particular qualities, 1669.—14. Considerations on the usefulness of experimental and natural philosophy, the 2d part, 1671.—15. A collection of tracts on several useful and important points of practical philosophy, 1671.—16. An essay on the origin and virtues of gems, 1672.—17. A collection of tracts on the relation between flame and air; and several other useful and curious subjects, 1672; besides furnishing, in this and the former year, a number of short dissertations on various topics, addressed to the Royal Society, and inserted in their Transactions.—18. Essays on the strange subtlety, great efficacy, and determinate nature, of effluvia; with a variety of experiments on other subjects, 1673.—19. The excellency of theology compared with philosophy, 1673. This discourse was written in the year 1665, while our author, to avoid the great plague which then raged in London, was forced to go from place to place in the country, having little or no opportunity of consulting his books.—20. A collection of tracts on the saltiness of the sea, the moisture of the air, the natural and preternatural state of bodies; to which is prefixed a dialogue concerning cold, 1674.—21. A collection of tracts containing suspicions about hidden qualities of the air; with an appendix touching celestial magnets; animadversions on Mr. Hobbes's problem concerning a vacuum; a discourse of the cause of attraction and suction, 1674.—22. Some considerations about the reasonableness of reason and religion; by T. E. (the final letters of his names). To which is annexed a discourse about the possibility of the resurrection; by Mr. Boyle, 1675. The same year several papers communicated to the Royal Society, among which were two upon quicksilver growing hot with gold.—23. Experiments and notes about the mechanical origin or production of particular qualities, in several discourses on a great variety of subjects, and among the rest on electricity, 1676.—He then communicated to Mr. Hook a short memoir of some observations made on an artificial substance that shines without any preceding illustration; published by Hook in his *Lectiones Cutlerianæ*.—24. Historical account of a degradation of gold made by an anti-elixir.—25. Aerial noctiluca; or some new phenomena, and a process of a fictitious self-shining substance, 1680. This year the Royal Society, as a proof of the just sense of his great worth, and of the constant and particular services which through a course of many years he had done them, made choice of him for their president; but he being extremely, and, as he says, peculiarly tender in point of oaths, declined that honour.—26. Discourse of things above reason; inquiring, whether a philosopher should admit any such, 1681.—27. New experiments and observations on the icy noctiluca; to which is added a chemical paradox, grounded on new experiments, making it probable that chemical principles are transmutable, so that out of one

of them others may be produced, 1682.—28. A continuation of new experiments, physico-mechanical, touching the spring and weight of the air, and their effects, 1682.—29. A short letter to Dr. Beale, in relation to the making of fresh water out of salt, 1683.—30. Memoirs for the natural history of human blood, especially the spirit of that liquor, 1684.—31. Experiments and considerations about the porosity of bodies, 1684.—32. Short memoirs for the natural experimental history of mineral waters, &c, 1685.—33. An essay on the great effects of even languid and unheeded motion, &c, 1685.—34. Of the reconcileableness of specific medicines to the corpuscular philosophy, &c, 1685.—35. Of the high veneration man's intellect owes to God, peculiarly for his wisdom and power, 1685.—36. Free inquiry into the vulgarly received notion of nature, 1686.—37. The martyrdom of Theodora and Didymia, 1687; a work he had drawn up in his youth.—38. A disquisition about the final causes of natural things, and about vivified light, 1688.

Mr. Boyle's health declining very fast, he abridged greatly his time given to conversations and communications with other persons, that he might have more time to prepare for the press some others of his papers, before his death, which were as follow:—39. Medicina Hydrostatica, &c, 1690.—40. The Christian Virtuoso, &c, 1690.—41. Experimenta et Observations Physice, &c, 1691; which is the last work that he published.

Mr. Boyle died on the last day of December of the same year, 1691, in the 65th year of his age, and was buried in St. Martin's church in the Fields, Westminster; his funeral sermon being preached by Dr. Gilbert Burnet, bishop of Salisbury; in which he displayed the excellent qualities of our author, with many circumstances of his life, &c. But as the limits of this work will not allow us to follow the bishop in the copious and eloquent account he has given of this great man's abilities, we must content ourselves with adding the following short eulogium by the celebrated physician, philosopher, and chemist, Dr. Boerhaave; who, after having declared Lord Bacon to be the father of experimental philosophy, asserts, that, "Mr. Boyle, the ornament of his age and country, succeeded to the genius and inquiries of the great chancellor Verulam. Which," says he, "of Mr. Boyle's writings shall I recommend? All of them. To him we owe the secrets of fire, air, water, animals, vegetables, fossils: so that from his works may be deduced the whole system of natural knowledge."

Mr. Boyle left also several papers behind him, which have been published since his death. Beautiful editions of all his works have been printed at London, in 5 volumes folio, and 6 volumes 4to. Dr. Shaw also published in 3 volumes 4to, the same works "abridged, methodized, and disposed under the general heads of Physics, Statics, Pneumatics, Natural History, Chemistry, and Medicine;" to which he has prefixed a short catalogue of the philosophical writings, according to the order of time when they were first published, as follows:

Physico-mechanical experiments on the spring and weight of the air	-	-	1661
The Sceptical Chemist	-	-	1661
Physiological Essays	-	-	1662
History of Colours	-	-	1663
Usefulness of Experimental Philosophy	-	-	1663
History of Cold	-	-	1665
Historical Paradoxes	-	-	1666
Origin of Forms and Qualities	-	-	1666

Cosmical Qualities	-	-	1670
The admirable Rarefaction of the Air	-	-	1670
The Origin and Virtues of Gems	-	-	1672
The Relation betwixt Flame and Air	-	-	1672
Effluviums	-	-	1673
Saltiness of the Sea	-	-	1674
Hidden Qualities of the Air	-	-	1674
The Excellence, &c, of the Mechanical Hypothesis	-	-	1674
Considerations on the Resurrection	-	-	1675
Particular Qualities	-	-	1676

BRACE, in Architecture, denotes a piece of timber, framed in with bevel-joints; serving to keep the building from swerving either way.

BRACHMINS, or BRACHMANS, a branch of the ancient Gymnosophists, or philosophers of India, remarkable for the severity of their lives and manners.

BRACKET, in Building, denotes a kind of wooden stay, in form of a knee or shoulder, serving for the support of shelves, &c, or a cramping-iron, which serves as a stay in timber-work.

BRADLEY (DR. JAMES), a celebrated English astronomer, the third son of William Bradley, was born at Sherborne in Gloucestershire in the year 1692. He was fitted for the university at Northleach, in the same county, at the boarding-school of Mr. Illes and Mr. Brice. From thence he was sent to Oxford, and admitted a commoner of Balliol college, March 15, 1710; where he took the degree of bachelor the 14th of October 1714, and of master of arts the 21st of January, 1716. His friends intending him for the church, his studies were regulated with that view; and as soon as he was of a proper age to receive holy orders, the bishop of Hereford, who had entertained great esteem for him, gave him the living of Bridstow, and soon after he was inducted to that of Landewy. Welfrey in Pembrokeshire.

He was nephew to Mr. Pound, a gentleman well known in the learned world, by many excellent astronomical and other observations, and who would have enriched it much more, if the journals of his voyages had not been burnt at Pudor Condor, when the place was set on fire, and the English who were settled there cruelly massacred. Mr. Pound himself very narrowly escaping with his life. With this gentleman, at Wanstead, Mr. Bradley passed all the time that he could spare from the duties of his function, being then sufficiently acquainted with the mathematics to improve by Mr. Pound's conversation. It may easily be imagined that the example and conversation of this gentleman did not render Bradley more fond of his profession, to

which he had before no great attachment: he continued however as yet to fulfil the duties of it, though at this time he had made such observations as laid the foundation of those discoveries which afterwards distinguished him as one of the greatest astronomers of his age. These observations gained him the notice and friendship of the lord-chancellor Macclesfield, Mr. Newton, afterwards Sir Isaac, Mr. Halley, and many other members of the Royal Society into which he was soon after elected a member.

Soon after, the chair of Savilian professor of astronomy at Oxford became vacant, by the death of the celebrated Dr. John Keil; and Mr. Bradley was elected to succeed him on the 31st of October, 1721, at 29 years of age: his colleague being Mr. Halley, who was professor of geometry on the same foundation. On this appointment Mr. Bradley resigned his church livings, and applied himself wholly to the study of his favourite science. In the course of his observations, which were innumerable, he discovered and settled the laws of the alterations of the fixed stars, from the progressive motion of light, combined with the earth's annual motion about the sun, and the nutation of the earth's axis, arising from the unequal attraction of the sun and moon on the different parts of the earth. The former of these effects is called the Aberration of the fixed stars, the theory of which he published in 1727; and the latter the Nutation of the earth's axis, the theory of which appeared in 1747, deduced from 20 years' assiduous observations, by which he communicated to the world two of the finest discoveries in modern astronomy, making a memorable epoch in the history of that science. See ABERRATION and NUTATION.

In 1730 Bradley succeeded Mr. Whiteside, as lecturer in astronomy and experimental philosophy in the Museum at Oxford; which was a considerable emolument to him, and which he enjoyed till within a year or two of his death, when the ill state of his health induced him to resign it.

Our author always preserved the esteem and friendship of Dr. Halley; who, being worn out by age and infirmities, thought he could not do better for the service of astronomy, than procure for Mr. Bradley the place of regius professor of astronomy at Greenwich, which he himself had many years possessed with the greatest reputation. With this view he wrote many letters, desiring Mr. Bradley's permission to apply for a grant of the reversion of it to him, and even offered to resign it in his favour, if it should be thought necessary; but Dr. Halley died before he could accomplish this kind object. Bradley however obtained the place, by the interest of lord Macclesfield, who was afterwards president of the Royal Society; and upon this appointment the university of Oxford conferred on him a diploma.

The appointment of astronomer royal at Greenwich, which was dated the 3d of February, 1741-2, placed our author in his proper sphere; and he pursued his observations with unwearyed diligence. However numerous the collection of astronomical instruments at that observatory, it was impossible that such an observer as Dr. Bradley should not desire to increase them, as well to answer those particular views, as in general to make observations with greater exactness. In the year 1748, therefore, he took the opportunity of the visit of the Royal Society to the observatory, annually made to examine the instruments and receive the professor's observations for the year, to represent so strongly the necessity of repairing the old instruments and providing new ones, that the society thought

proper to make application to the king, who was pleased to order 1000 pounds for that purpose. This sum was laid out under the direction of Bradley, who, with the assistance of the late celebrated Mr. Graham and Mr. Bird, furnished the observatory with as complete a collection of astronomical instruments, as the most skilful and diligent observer could desire. Our author being thus furnished with such assistance, pursued his observations with great assiduity during the rest of his life; an immense number of which was found after his death, in 13 folio volumes, and were presented to the university of Oxford in 1776, on condition of their printing and publishing them.

During Dr. Bradley's residence at the Royal Observatory, the living of the church at Greenwich became vacant, and was offered to him: upon his refusing to accept it, from a conscientious scruple, "that the duty of a pastor was incompatible with his other studies and necessary engagements," the king was pleased to grant him a pension of £50/- over and above the astronomer's original salary (100/-) from the Board of Ordnance, "in consideration (as the sign manual, dated the 15th Feb. 1752, expresses it) of his great skill and knowledge in the several branches of astronomy and other parts of the mathematics, which have proved so useful to the trade and navigation of this kingdom;" a pension which has been regularly continued to the astronomer royal ever since.

About 1748, our author became entitled to bishop Crew's benefaction of 30/- a year, to the lecture reader in experimental philosophy at Oxford. He was elected a member of the academy of Sciences at Berlin in 1747; of that at Paris, in 1748; of that at Petersburg, in 1754; and of that at Bologna, in 1757. He was married in the year 1744, but never had more than one child, a daughter.

By his unremitting application to study and observations, he became afflicted, for near two years before his death, with a violent oppression on his spirits, which interrupted his useful labours. This distress arose chiefly from an apprehension that he should outlive his rational faculties; but this so much dreaded evil never came upon him. In June 1762 he was seized with a suppression of urine, occasioned by an inflammation in the reins, which terminated his existence the 13th of July following. His death happened at Chalford in Gloucestershire, in the 70th year of his age; and he was interred at Minchinhampton in the same county.

As to the character of Dr. Bradley, he was remarkable for a placid and gentle modesty, very uncommon in persons of an active temper and robust constitution. Though he was a good speaker, and possessed the rare but happy art of expressing his ideas with the utmost precision and clearness, yet no man was a greater lover of silence, for he never spoke but when he thought it absolutely necessary. Nor was he more inclined to write than to speak, as he has published very little: he had a natural diffidence, which made him always afraid that his works might injure his character; so that he suppressed many which might have been worthy of publication.

His papers, which have been inserted in the Philos. Trans. are,

1. Observations on the Comet of 1723, vol. 33, p. 41.—
2. The Longitude of Lisbon and of the Fort of New York from Wanstead and London determined by the Eclipse of the First Satellite of Jupiter, vol. 34, p. 85.—3. An Account of a new discovered Motion of the Fixed Stars, vol. 35, p. 637.—4. On the Going of Clocks with Isochronical

Pendulums, vol. 38, p. 302.—5. Observations on the Comet of 1736—7, vol. 40, p. 111.—6. On the Apparent Motion of the Fixed Stars, vol. 45, p. 1.—7. On the Occultation of Venus by the Moon, the 15th of April, 1751, vol. 46, p. 201.—8. On the Comet of 1757, vol. 50, p. 408.—9. Directions for Using the Common Micrometer, vol. 62, p. 46.

BRADWARDIN (*THOMAS*), a skilful mathematician and divine, was born at Hartfield in Sussex, about the close of the 13th century. He was educated at Merton-college, Oxford, where he took the degree of doctor of divinity. It has been said he was professor of divinity at Oxford; that he was chancellor of the diocese of London, and confessor to Edward the 3d, whom he constantly attended during his war with France. After his return from the field, he was made prebendary of Lincoln, and afterward archbishop of Canterbury. He died at Lambeth in the year 1349, forty days after his consecration. His works are, 1. *De Causa Dei*, printed in London, 1618, published by J. H. Savil.—2. *De Geometria Speculativa, &c.* Paris, 1495, 1512, 1530.—3. *De Arithmetica Practica*. Paris, 1502, 1512.—4. *De Proportionibus*. Paris, 1495. Venice, 1505, folio.—5. *De Quadratatura Circuli*. Paris, 1495, fol.

BRAHE (*TYCNO*), a celebrated astronomer, descended from a noble family, originally of Sweden, but settled in Denmark, was born the 14th of December 1546, at Knudstorp in the county of Schonen, near Helsimbourg. He was taught Latin when 7 years old, and studied 5 years under private tutors. His father dying while he was very young, his uncle, George Brahe, having no children, adopted him, and sent him, in 1559, to study philosophy and rhetoric at Copenhagen. The great eclipse of the sun, on the 21st of August 1650, happening at the precise time the astronomers had foretold, he began to consider astronomy as something divine; and purchasing the tables of Stadius, he gained some notion of the theory of the planets. In 1562 he was sent by his uncle to Leipsic to study the law, where his acquirements gave manifest indications of extraordinary abilities. His natural inclination however was to the study of the heavens, to which he applied himself so assiduously, that, notwithstanding the care of his tutor to keep him close to the study of the law, he made use of every means in his power for improving his knowledge of astronomy; he purchased with his pocket-money whatever books he could meet with on this subject, and read them with great attention, procuring assistance in difficult cases from Bartholomew Scultens, his private tutor; and having procured a small celestial globe, he took opportunities, when his tutor was in bed, and when the weather was clear, to examine the constellations in the heavens, to learn their names from the globe, and their motions from observation.

After a course of 3 years study at Leipsic, his uncle dying, he returned home in 1565. In this year a difference arising between Brahe and a Danish nobleman, they fought, and our author lost part of his nose cut off by a blow in the contest. This defect he so artfully supplied with one made of precious metal and wax, that it was not perceptible. About this time he began to apply himself to chemistry, proposing nothing less than to obtain the philosopher's stone. But becoming greatly disgusted to see the liberal arts despised, and finding his own relations and friends uneasy that he applied himself to astronomy, as thinking it a study unsuitable to a person of his quality,

he went to Wirtemberg in 1566, from which the breaking out of the plague soon occasioned his removal to Rostock, and in 1569 to Augsburg, where he was visited by Peter Ramus, then professor of astronomy at Paris, and who greatly admired his uncommon skill in this science.

In 1571 he returned to Denmark; and was favoured by his maternal uncle, Steno Billes, a lover of learning, with a convenient place at his castle of Herritzvad near Knudstorp, for making his observations, and building a laboratory. And here it was he discovered, in 1573, a new star in the constellation Cassiopeia. But soon after, his marrying a country girl, beneath his rank, occasioned so violent a quarrel between him and his relations, that the king was obliged to interpose to reconcile them.

In 1574, by the king's command, he read lectures at Copenhagen on the theory of the planets. The year following he began his travels through Germany, and proceeded as far as Venice. He then resolved to remove his family, and settle at Basil; but Frederick the 2d, king of Denmark, being informed of his design, and unwilling to lose a man who was capable of doing so much honour to his country, he promised to enable him to pursue his studies, and bestowed on him for life the island of Huen in the Sound, and engaged that an observatory and laboratory should be built for him, with a supply of money for carrying on his designs: accordingly the first stone of the observatory was laid the 8th of August 1576, under the name of Uranibourg. The king also gave him a pension of 2000 crowns out of his treasury, a fee in Norway, and a canonry of Roschild, which amounted to 1000 more. This situation he enjoyed about 20 years, pursuing his observations and studies with great industry: here he kept always in his house ten or twelve young men, who assisted him in his observations, and whom he instructed in astronomy and mathematics. And it was also at this place that he received a visit from James vi, king of Scotland, afterwards James i of England, having come to Denmark to espouse Anne, daughter of Frederick ii. This king made our author some noble presents, and wrote a copy of Latin verses in his praise.

Brahe's tranquillity however in this happy situation was at length fatally interrupted. Soon after the death of King Frederick, by the aspersions of envious and malevolent ministers, he was deprived of his pension, fee, and canonry, in 1596. Being thus rendered incapable of supporting the expenses of his establishment, he quitted his favourite Uranibourg, and withdrew to Copenhagen, with some of his instruments, and continued his astronomical observations and chemical experiments in that city, till the same malevolence procured from the new king, Charles iv, an order for him to discontinue them. This induced him to fall upon means of being introduced to the emperor Rodolphus, who was fond of mechanism and chemical experiments: and to smooth the way to an interview, Tycho now published his book, *Astronomia instaurata Mechanica*, adorned with figures, and dedicated it to the emperor. That prince received him at Prague with great civility and respect; gave him a magnificent house, till he could procure one for him more fit for astronomical observations; he also assigned him a pension of 3000 crowns; and promised him a fee for himself and his descendants. Here then he settled in the latter part of 1598, with his sons and scholars, and among them the celebrated Kepler, who had joined him. But he did not

long enjoy this happy situation; for, about 3 years after, he died, on the 24th of October 1601, of a retention of urine, in the 55th year of his age, and was interred in a magnificent manner in the principal church at Prague, where a noble monument was erected to his memory; leaving, besides his wife, two sons and four daughters. On the approach of death, he enjoined his sons to take care that none of his works should be lost; exhorted the students to attend closely to their exercises; and recommended to Kepler the finishing of the Rodolphine tables, which he had constructed for regulating the motion of the planets.

Brahé's skill in astronomy is universally known; and he is famed for being the inventor of a new system of the planets, which he endeavoured, though without success, to establish on the ruins of that of Copernicus. He was very credulous with regard to judicial astrology and presages. If he met an old woman when he went out of doors, or a hare upon the road on a journey, he would turn back immediately, being persuaded that it was a bad omen: also, when he lived at Uranibourg, he kept in his house a madman, whom he generally placed at his feet at table; for as he imagined that every thing spoken by mad persons presaged something, he carefully observed all that this man said; and because it sometimes proved true, he fancied it might always be depended on. He was of a very irritable disposition: a mere trifle would put him in a passion; and against persons of the first rank, whom he thought his enemies, he openly discovered his resentment. He was very apt to rally others, but highly provoked when the same liberty was taken with himself.—The principal part of his writings, according to Gassendus, are,

1. An account of the New Star, which appeared Nov. 11th, 1572, in Cassiopeia; Copenh. 1573, in 4to.—2. An Oration concerning the Mathematical Sciences, pronounced in the university of Copenhagen, in the year 1574: published by Conrad Aslac, of Bergen in Norway.—3. A treatise on the Comet of the year 1577, immediately after it disappeared. Nine years afterwards he revised it, and added a 10th chapter; printed at Uranibourg, 1589.—4. Another treatise on the New Phenomena of the heavens. In the first part of which he treats of the Restitution, as he calls it, of the sun, and of the fixed stars. And in the 2d part, of a New Star, which had then made its appearance.—5. A collection of Astronomical Epistles: printed in 4to, at Uranibourg in 1596; at Nuremberg in 1602; and at Frankfort in 1610. It was dedicated to Maurice Landgrave of Hesse; because there is in it a considerable number of letters of the Landgrave William his father, and of Christopher Rothmann, the mathematician of that prince, to Tycho, and of Tycho to them.—6. The Mechanical Principles of Astronomy restored: Wandesburg, 1598, in folio.—7. An Answer to the Letter of a certain Scotchman, concerning the comet, in the year 1577.—8. On the composition of an Elixir for the plague; addressed to the emperor Rodolphus.—9. An Elegy on his Exile: Rostock, 1614, 4to.—10. The Rodolphine Tables; which he had not finished when he died; but were revised, and published by Kepler, as Tycho had desired.—11. An Accurate Enumeration of the Fixed Stars: addressed to the emperor Rodolphus.—12. A complete Catalogue of 1000 of the fixed Stars; which Kepler has inserted in the Rodolphine Tables.—13. Historia Coelestis; or a History of the Heavens; in two parts. The 1st contains the Observations he had made at Urani-

bourg, in 16 books; the latter contains the Observations made at Wandesburg, Wittemberg, Prague, &c.; in 4 books.—14. Is an Epistle to Caster Pucer; printed at Copenhagen 1668.

BRANCKER, or BRANKER (THOMAS), an eminent mathematician of the 17th century, son of Thomas Brancker some time bachelor of arts in Exeter-college, Oxford, was born in Devonshire in 1636, and was admitted butler of the said college, Nov. 8, 1652, in the 17th year of his age. In 1655, June the 15th, he took the degree of bachelor of arts, and was elected probationary-fellow the 30th of the same month. In 1658, April the 22d, he took the degree of master of arts, and became a preacher; but after the Restoration, refusing to conform to the ceremonies of the church of England, he quitted his fellowship in 1662, and retired to Chester: but not long after, he became reconciled to the service of the church, took orders from a bishop, and was made a minister of Whitegate. He had however, for some time, enjoyed great opportunity and leisure for pursuing the bent of his genius in the mathematical sciences; and his skill both in the mathematics and chemistry procured him the favour of Lord Brereton, who gave him the rectory of Tilston. He was afterward chosen master of the well-endowed school at Macclesfield, in that county, where he spent the few remaining years of his life, which was terminated by a short illness in 1676, at 40 years of age; and was interred in the church at Macclesfield.

Brancker wrote a piece on the Doctrine of the Sphere, in Latin, which was published at Oxford in 1662; and in 1668 he published at London, in 4to, a translation of Rhonius's Algebra, with the title of An Introduction to Algebra; which treatise having been communicated to Dr. John Pell, he received from him some assistance towards improving it; which he generously acknowledges in a letter to Mr. John Collins; with whom, and some other gentlemen, proficients in this science, he continued a correspondence during his life.

BREACH, in Fortification, a gap or opening made in any part of the works of the town, by the cannon or mines of the besiegers, with intent to storm or attack the place.

BREAKING Ground, in Military Affairs, is beginning the works for carrying on the siege of a place; more especially the commencement of digging trenches, or approaches.

BREAST-WORK, in the Military Art, is an elevation of earth thrown up around a fortified place or post, to conceal or protect the garrison, and which is at the same time so strong that the enemy's shot cannot pierce through it. See PARAPET.

BREECH of a Gun, the hinder part, from the cascabel to the lower part of the bore.

BREREWOOD (EDWARD), a learned mathematician and antiquary, was the son of Robert Brerewood, a reputable tradesman, who was three times mayor of Chester. Our author was born in that city in 1565, where he was educated in grammar erudition at the free-school; and was afterward admitted, in 1581, of Brazen-nose college, Oxford, where he soon acquired the character of a hard student; as he has shown in his commentaries on Aristotle's Ethics, which he produced about the age of 21.

In the year 1596 he was chosen the first professor of astronomy in Gresham-college, being one of the two who, at the desire of the electors, were recommended to them

by the university of Oxford. He loved retirement, and entirely devoted himself to the pursuit of knowledge. And though he never published any thing himself, yet he was very communicative, and ready to impart what he knew, to others, either in conversation or in writing. His retired situation at Gresham-college being agreeable, it did not appear that he had any other views, but continued there the remainder of his life, which was terminated by a fever the 4th of November 1613, at 48 years of age, in the midst of his pursuits, and before he had taken proper care to collect and digest his learned labours; which however were not lost; being reduced to order, and published after his death. These were little or nothing mathematical, being of a miscellaneous nature, on the several subjects of Weights, Money, Languages, Religion, Logic, the Sabbath, Meteors, the Eye, Ethics, &c.

BRIDGE, a work of carpentry or masonry, built over a river, canal, or the like, for the convenience of passing from one side to the other; and may be considered as a road over water, supported by one or more arches, and these again supported by proper piers or butments. Besides these essential parts, may be added the paving at top, the banquet, or raised footway, on each side, leaving a sufficient breadth in the middle for horses and carriages, also the parapet wall either with or without a balustrade, or other ornamental and useful parts. The breadth of a bridge for a great city should be such, as to allow an easy passage for three carriages and two horsemen abreast in the middle way, and for 3 foot passengers in the same manner on each banquet: but for other smaller bridges, a less breadth may suffice.

Bridges are commonly very difficult to execute, on account of the inconvenience of laying foundations and walling under water. The earliest rules and instructions for building of bridges are given by Alberti, in his Archit. 1, 8. Other rules were afterwards laid down by Palladio, Serlio, and Scamozzi, which are collected by Blondel, in his Cours d'Archit. pa. 629, &c. The best of these rules were also given by Goldman, Baukhurst, and in Hawkesmoor's History of London Bridge. M. Gautier has a considerable volume expressively on bridges, ancient and modern. See also Riou's Short Principles for the Architecture of Stone Bridges; as also Emerson, Muller, Labelye, and my own Principles of Bridges, in the 1st vol. of my Tracts, besides neat accounts in the various new Encyclopedias, as well as several French authors.

The conditions required in a bridge are, That it be well designed, commodious, durable, and suitably decorated. It should be of such a height as to be quite convenient for the passage over it, and yet easily admitting through its arches the vessels that navigate under it, and also the water, even at high tides and floods; the neglect of this precept has caused the destruction of many bridges. Bridges are commonly continued in a straight direction perpendicular to the stream; though some think they should be made rather convex towards the stream, the better to resist floods, &c. And bridges of this sort have been executed in some places, as Pont St. Esprit near Lyons. Again, a bridge should not be made in too narrow a part of a navigable river, or one that is subject to tides or floods; because the breadth being still more contracted by the piers, this will increase the depth, velocity, and fall of the water under the arches, and endanger the whole bridge and navigation. There ought to be an uneven number of arches, or an even number of piers; both that the middle of the stream or

chief current may flow freely without the interruption of a pier; and that the two halves of the bridge, by gradually rising from the ends to the middle, may there meet in the highest and largest arch; and also, that by being open in the middle, the eye in viewing it may have a better command and look directly through there. When the middle and ends are of different heights, their difference however ought not to be great in proportion to the length, that the ascent and descent may be easy; and in that case also it is more beautiful to make the top in one continued curve than two straight lines forming an angle in the middle. Bridges should rather be of few and large arches, than of many smaller ones, if the height and situation will possibly admit of it; for this will leave passage for the water and navigation, and be a great saving in materials and labour, as there will be fewer piers and centres, and the arches &c will require less materials; a remarkable instance of which appears in the difference between the bridges of Westminster and Blackfriars, the expense of the former being more than double the latter.

For the proper execution of a bridge, and making an estimate of the expense &c, it is necessary to have three plans, three sections, and an elevation. The three plans are so many horizontal sections, viz, 1st a plan of the foundation under the piers, with the particular circumstances attending it, whether of gratings, planks, piles, &c; the 2d is the plan of the piers and arches; and the 3d is the plan of the superstructure, with the paved road and banquet. The three sections are vertical ones; the 1st of them a longitudinal section from end to end of the bridge, and through the middle of the breadth; the 2d a transverse one, or across it, and through the summit of an arch; and the 3d also across, but taken upon a pier. The elevation is an orthographic projection of one side or face of the bridge, or its appearance as viewed at a distance, showing the exterior aspect of the materials, with the manner in which they are disposed, &c.

For the figure of the arches, some prefer the semicircle, though perhaps without any just reason; others the elliptical form, as having many advantages over the semicircular; and some talk of the catenarian arch, though its pretended advantages are only chimerical; but the arch of equilibration is the only perfect one, so as to be equally strong in every part: see my Principles of Bridges. The piers are of divers thickness, according to the figure, span, and height of the arches; as may be seen in the work above mentioned.

With the Romans, the repairing and building of bridges were committed to the priests, thence named Pontifices; next to the censors, or curators of the roads; but at last the emperors took the care of the bridges to themselves. Thus the Pons Janiculensis was built of marble by Antoninus Pius; the Pons Cestius was restored by Gordian; and Arian built a new one, which was called after his own name. In the middle age, bridge-building was reckoned among the acts of religion; and, towards the end of the 12th century, St. Benezet founded a regular order of hospitallers, under the name Pontifices, or bridge-builders, whose office was to assist travellers, by making bridges, settling ferries, and receiving strangers into hospitals, or houses, built on the banks of rivers. We read of an hospital of this kind at Avignon, where the hospitallers resided under the direction of their first superior St. Benezet: and the Jesuit Raynaldus has a treatise on St. John the bridge-builder.

Among the bridges of antiquity, that built by Trajan over the Danube is the most magnificent. It was demolished by his next successor Adrian, the ruins of which are still to be seen in the middle of the Danube, near the city Warhel in Hungary. It had 20 piers, of square stone, each of which was 150 feet high above the foundation, 60 feet in breadth, and 170 feet distant from one another, which is the span or width of the arches; so that the whole length of the bridge was more than 1530 yards, or one mile nearly.

In France, the Pont de Garde is a very bold structure; the piers being only 13 feet thick, yet serving to support an immense weight of a triplicate arcade, and joining two mountains. It consists of three bridges, one over another; the uppermost of which is an aqueduct, which carries water to Nismes.

The aqueduct bridge of Alcantara, near the city of Lisbon, which was finished in 1732, is also a very magnificent piece of workmanship; it consists of 35 arches, the largest of which is 227 feet high, and 108 $\frac{1}{2}$ feet wide.

The bridge of Avignon, which was finished in the year 1188, consists of 18 arches, and measures 1340 paces, or about 1000 yards in length.

Over the several canals at Venice are laid nearly 500 bridges of different sizes; the greater number of them are of stone. The chief of these, called the *Rialto*, is celebrated as a master-piece of art: it consists of one flat and bold arch, nearly 100 feet span, and only 23 feet high above the water; it was built in 1591 from a design of Michael Angelo. The breadth of the bridge, which is 43 feet, is divided by two rows of shops into three narrow streets, that in the middle being the widest; and there is in the centre an open arch-way, by which the three streets communicate with one another. At each end of the Rialto is an ascent of 56 steps; the view from its summit is very lively and magnificent. The whole interior of the shops and the bridge is of marble. The foundation extends 90 feet, and rests upon 12000 elm piles. This structure cost the republic 250,000 ducats. Poulet also mentions a bridge of a single arch, in the city of Munster in Bothnia, much nobler than that of the Rialto at Venice. Yet these are nothing to a bridge in China, built from one mountain to another, consisting only of a single arch, 400 cubits long, and 500 cubits high, whence it is called the flying bridge; a figure of which is given in the Philos. Trans. Kircher also speaks of a bridge in the same country 360 perches long without any arch, but supported by 300 pillars.

There are many bridges of considerable note in our own country. The triangular bridge at Crowland in Lincolnshire, is esteemed the most ancient Gothic structure remaining entire in the kingdom; and was erected about the year 860.

London bridge is on the old Gothic structure, with 20 small locks or arches, each of about 20 feet wide; but there are now only 18 open, two having lately been thrown into one in the centre, and another on one side is concealed or covered up. It is 900 feet long, 60 high, and 74 wide; the piers are from 25 to 34 feet broad, with starlings projecting at the ends: so that the greatest water-way, when the tide is above the starlings, was 450 feet, scarce half the breadth of the river; and below the starlings, the water-way was reduced to 194 feet, before the late opening of the centre. London bridge was first built with timber between the years 993 and 1016; and it was

repaired, or rather rebuilt with timber in 1163. The stone bridge was begun in 1176, and finished in 1209. It is probable there were no houses on this bridge for upwards of 200 years; since we read of a tilt and tournament held on it in 1395. Houses it appears were erected on it afterwards; but being found of great inconvenience and nuisance, they were removed in 1758, and the avenues to it also enlarged, and the whole made more commodious; the two middle arches were then thrown into one, by removing the pier from between them; the whole amounting to above 80,000*l.*

There were other bridges in England built in the old manner of London bridge; as the bridge at Rochester, which is 550 feet long, and has 11 arches; also the late bridge at Newcastle-upon-Tyne, which was broken down by a great flood in the year 1771, for want of a sufficient quantity of water-way through the arches.

The longest bridge in England is that over the Trent at Burton, built in the 12th century, of squared free-stone, and is strong and lofty; it contains 34 arches, and the whole length is 1545 feet. But this falls far short of the wooden bridge over the Drave, which according to Dr. Brown is at least 5 miles long.

But one of the most singular bridges in Europe is that built over the Taaf in Glamorganshire, by William Edwards, a poor country mason, in the year 1756. This remarkable bridge consists of but one stupendous arch, which, though only 8 feet broad, and 35 feet high, is no less than 140 span, being part of a circle of 175 feet diameter.

There is also a remarkable bridge of one arch, built at Colebrook Dale in 1779, of cast-iron: and another still larger of the same metal, raised over the river Wear, at Sunderland, the arch being of 240 feet span. And since that time several other iron bridges have been erected in various places, accounts and drawings of which may be seen in my Tracts before noticed.

Of modern bridges, perhaps the two finest in Europe are those of Westminster and Blackfriars over the river Thames at London. The former is 1220 feet long, and 44 feet wide, having a commodious broad foot-path on each side for passengers. It consists of 13 large and two small arches, all semicircular, with 14 intermediate piers. The arches all spring from about 2 feet above low-water mark; the middle arch is 76 feet wide, and the others on each side decrease regularly by 4 feet at a time. The two middle piers are each 17 feet thick at the springing of the arches; and the others decrease equally on each side by one foot at a time; every pier terminating with a salient right angle against either stream. This bridge is built of the best materials, and in a neat and elegant taste, but the arches are too small for the quantity of masonry contained in it. This bridge was begun in 1738, and opened in 1750; the whole sum of money granted and paid for the erection of it, with the purchase of houses to take down, and widening the avenues, &c., amounted to 389,500*l.*

Blackfriars bridge, nearly opposite the centre of the city of London, was begun in 1760, and completed in 10 years and three quarters; it is an exceeding light and elegant structure, but the materials unfortunately do not seem to be of the best sort, as many of the arch stones are decaying. It consists of 9 large, elegant, elliptical arches; the centre arch being 100 feet wide, and those on each side decreasing in a regular gradation to the smallest, at each extremity, which is 70 feet wide. The breadth of the

bridge is 42 feet, and the length from wharf to wharf 995. The upper surface is a portion of a very large circle, which forms an elegant figure, and is of convenient passage over it. The whole expense was 150,840l.

Wooden BRIDGES. The simplest case of these edifices, is that in which the road-way is laid over beams placed horizontally, and supported at each end by piers or posts. This method however is deficient in strength and width of opening: it is therefore necessary, in all works of any magnitude, to apply the principles of trussing, as used in roofs and arches. Wooden bridges of this kind are stiff frames of carpentry, in which, by a proper disposition, beams are put so as to stand instead of solid bodies, as large as the spaces which the beams enclose; and thus two or three more of these are set in abutment with each other, like mighty arch stones.

Palladio has given several very elegant designs of wooden bridges; one of which is that over the river Cismoine. The river where this bridge is erected, is 100 feet wide; this width is divided into six equal parts; and at the end of each part, excepting at the banks, which are strengthened with pilasters of stone, the beams are placed that form the breadth of the bridge, upon which, a little space being left at their ends, were placed other beams lengthwise, which form the sides. Over these, directly upon the first, the *colonelli* (king-posts) were disposed on each side; these king-posts are connected to the beams which form the breadth of the bridge, by means of irons passing through the projecting ends of the beams, and bolted and pinned through both.

Mr. Coxe, in the first volume of his Travels, has slightly described a very singular bridge at Wittingen in Switzerland; the construction of which is quite simple. The span is 230 feet, and it rises only 5. The arches approach to a catenarian form, built up of 7 courses of solid logs of oak, in lengths of 12 or 14 feet, and 16 inches or more in thickness. These are all picked of a natural shape, suited to the intended curve; so that the wood is no where cut across the grain to trim it into shape. These logs are laid above each other, so that their abutting joints are alternate like those of a brick wall; or, in the language of the workmen, they break joint. It is indeed a wooden structure simply built up by laying the pieces upon each other, taking care to make the abutting joints as close as possible. They are not fastened together by pins or bolts, but held united by iron straps, which surround them at the distance of 5 feet from each other, where they are fastened by bolts and keys. The two arches being erected and well butted against the rock on each side, were freed from their supports, and allowed to settle. They are so placed that the intended road intersects them about the middle of their height. The road-way is supported by cross-joints which rest on a long horizontal summer-beam; and this is connected with the arches on each side by uprights bolted into them. The whole is covered with a roof which projects over the arches on each side to defend them from the weather. Three of the spaces between these uprights have struts or braces, which give the upper work a sort of trussing in that part. This bridge is of strength much more than adequate to support any load that can be laid upon it; though it is manifest, by the attempts to truss the ends, that it was the contrivance of a person ignorant of principle. It was the work of one Ulrich Grubenhamm, of Tussen, in the canton of Appenzel, a carpenter without

education, but celebrated for several works of the same kind.

At Schaffhausen, in Switzerland, where the Rhine flows with great rapidity, several stone bridges had been destroyed, when in 1754 Grubenhamm offered to throw a wooden bridge of a single arch across the river, which is nearly 390 feet wide. The magistrates, however, required that it should consist of two arches, and that he should for that purpose employ the middle pier of the last stone bridge, which would divide the new one into two unequal arches, of 172 and 193 feet span. The carpenter did so, but contrived to leave it a matter of doubt whether the bridge is at all supported by the middle pier. It was erected on a plan nearly similar to the Wittingen bridge, at the expense of about 8000l. sterling. Travellers inform us, that it shook if a man passed over it; yet waggon heavily laden also went over it without danger. We are sorry to add that this curious bridge was burnt by the French when they evacuated Schaffhausen in April 1799.

Iron BRIDGES, are those in which iron is the chief material used. Iron bridges are the exclusive invention of British artists. The first that has been erected on a large scale, is that over the river Severn at Colebrook Dale, in Shropshire. This bridge is composed of 5 ribs, and each rib of 3 concentric arcs, connected together by radiating pieces. The interior arc forms a complete semicircle, but the others extend only to the cills under the road-way. These arcs pass through an upright frame of iron at each end, which serves as a guide; and the small space in the haunches between the frames and the outer arc is fitted in with a ring of about 7 feet diameter. Upon the top of the ribs are laid cast-iron plates, which sustain the roadway. The arch of this bridge is 100 feet 6 inches in span; the interior ring is cast in two pieces, each piece being about 70 feet in length. It was constructed in the year 1779, by Mr. Abraham Darby, iron-master at Colebrook Dale, and must be considered as a very bold effort in the first instance of adopting a new material. The total weight of the metal is 378½ tons.

The second iron bridge of which the particulars have come to our knowledge was that designed by Mr. Thomas Paine, author of many political works. It was constructed by Messrs. Walker at Rotherham, and was brought to London and set up in a bowling-green at Paddington, where it was exhibited for the first time. After which it was intended to have been sent to America; but Mr. Paine not being able to defray the expense, the manufacturers took it back, and the malleable iron was afterwards worked up in the construction of the bridge at Wearmouth.

The third iron bridge of importance erected in Great Britain, was that over the river Wear at Bishop Wearmouth, near Sunderland, the chief projector of which was Rowland Burton, esq. M. P. It consists of a single arch, whose span is 236 feet; and as the springing stones at each side project 2 feet, the whole opening is 240 feet. The arch is the segment of a circle of about 444 feet diameter, its versed sine is 34 feet, and the whole height from low water about 100 feet, admitting vessels of from 2 to 300 tons burthen to pass under it without striking their masts. A series of 105 blocks form a rib, and 6 of these ribs compose the breadth of the bridge. The spandrels, or the spaces between the arch and the road-way, are filled up with cast-iron circles which touch the outer circumference of the arch, and at the same time support the

road-way, thus gradually diminishing from the abutments towards the centre of the bridge. There are also diagonal iron bars, which are laid on the tops of the ribs and extended to the abutments, to keep the ribs from twisting. The superstructure is a strong frame of timber planked over to support the carriage-road, which is composed of marl, lime-stone, and gravel, with a cement of tar and chalk immediately upon the planks, to preserve them. The whole width of the bridge is 32 feet. The abutments are masses of almost solid masonry, 24 feet in thickness, 42 in breadth at bottom, and 37 at top. The south pier is founded on the solid rock, and rises from about 22 feet above the bed of the river. On the north side the ground was not so favourable, so that it was necessary to carry the foundation 10 feet below the bed. The weight of the iron in this extraordinary fabric amounts to 260 tons; 46 of these are malleable, and 214 cast. The entire expense was 27,000*l.*

Many other iron bridges have since been constructed or proposed by different persons, and in various situations, which are exhibited and described in the first volume of my Tracts.

There are various other kinds of bridges, besides these already mentioned, such as hanging or pendant bridges, draw-bridges, flying bridges, &c, &c, and even natural bridges, of which kind a most wonderful one is described by Mr. Jefferson, in his State of Virginia; and another described by Don Ulloa, in the province of Angariz, in South America. See also ARCH.

BRIGGS (HENRY), one of the greatest mathematicians in the 16th and 17th centuries, was born at Warleywood, near Halifax in Yorkshire, in 1556. From a grammar-school in that country he was sent to St. John's-college, Cambridge, in 1579; where after taking both the degrees in arts, he was chosen fellow of his college in 1588. He applied himself chiefly to the study of mathematics, in which he so greatly excelled, that in 1592 he was made examiner and lecturer in that faculty; and soon after, reader of the physical lecture, founded by Dr. Linacer.

On the settlement of Gresham-college, in London, he was chosen the first professor of geometry there, in 1596. Soon after this, he constructed a table, for finding the latitude, from the variation of the magnetic needle being given. In the year 1609 he contracted an acquaintance with the learned Mr. James Usher, afterwards archbishop of Armagh, which was continued many years after by letters, two of Mr. Briggs being still extant in the collection of Usher's letters that were published: in the former of these, dated August 1601, he writes, among other things, that he was engaged in the subject of eclipses; and in the latter, dated the 10th of March 1615, that he was wholly taken up and employed about the noble invention of logarithms, which had come out the year before, and in the improvement of which he had afterwards so great a concern. For Briggs immediately applied himself to the study and improvement of them; expounding them also to his auditors in his lectures at Gresham-college. In these lectures he proposed the alteration of the scale of logarithms, from the hyperbolic form which Lord Napier had given them, to that in which 1 should be the logarithm of the ratio of 10 to 1; and soon after he wrote to Lord Napier to make the same proposal to himself. In the year 1616 Briggs made a visit to Napier at Edinburgh, to confer with him on this change; and the next year he did the

same also. In these conferences, the alterations were agreed upon accordingly, and on Briggs's return from his second visit, in 1617, he published the first chiliad, or 1000 of his logarithms. See the Introduction to my Logarithms, for an ample history of these transactions.

In 1619 he was made the first Savilian professor of geometry at Oxford; and resigned the professorship of Gresham-college the 25th of July 1620. At Oxford he settled himself at Merton-college, where he continued a most laborious and studious life, employed partly in the duties of his office as geometry lecturer, and partly in the computation of the logarithms, and in other useful works. In the year 1622 he published a small tract on the "North-west passage to the South Seas, through the continent of Virginia and Hudson's Bay;" the reason of which was probably, that he was then a member of the company trading to Virginia. His next performance was his great and elaborate work, the Arithmetica Logarithmica in folio, printed at London in 1624; a stupendous work for so short a time! containing the logarithms of 30 thousand natural numbers, to 14 places of figures besides the index. Briggs lived also to complete a table of logarithmic sines and tangents for the 100th part of every degree to 14 places of figures, besides the index; with table of natural sines for the same 100th parts to 15 places, and the tangents and secants for the same to ten places; with the description and construction of the whole. These tables were printed at Gouda in 1631, under the care of Adrian Vlaci, and published in 1633, under the title of Trigonometria Britannica. In the construction of these two works, on the logarithms of numbers, and of sines and tangents, our author, besides extreme labour and application, manifests the highest power of genius and invention; as we here, for the first time, meet with several of the most important discoveries in the mathematics, and what have hitherto been considered as of much later invention; such as the Binomial Theorem; the Differential Method and Construction of Tables by Differences; the Interpolation by Differences; with Angular Sections, and several other ingenious compositions; a particular account of which may be seen in the Introduction to my Mathematical Tables.

This truly great man terminated his useful life the 26th of January 1630, and was buried in the choir of the chapel of Merton-college. As to his character, he was not less esteemed for his great sincerity and other eminent virtues, than for his excellent skill in mathematics. Doctor Smith gives him the character of a man of great probity; easy of access to all; free from arrogance, moroseness, envy, ambition, and avarice; a contemner of riches, and contented in his own situation; preferring a studious retirement to all the splendid circumstances of life. The learned Mr. Thomas Gataker, who attended his lectures when he was reader of mathematics at Cambridge, represents him as highly esteemed by all persons skilled in mathematics, both at home and abroad; and says, that desiring him once to give his judgment concerning judicial astrology, his answer was, "that he conceived it to be a mere system of groundless conceits." Oughtred calls him the mirror of the age, for his excellent skill in geometry. And one of his successors at Gresham-college, the learned Dr. Isaac Barrow, in his oration there upon his admission, has drawn his character more fully; celebrating his great abilities, skill, and industry, particularly in perfect-

ing the invention of logarithms, which, without his care and pains, might have continued an imperfect and useless design.

His writings were more important than numerous: some of them were published by other persons: the list of the principal part of them is as follows:

1. A Table to find the Height of the Pole; the Magnetical Declination being given. This was published in Mr. Thomas Blundeville's *Theoriques of the Seven Planets*; London 1602, 4to.

2. Tables for the Improvement of Navigation. These consist of, A table of declination to every minute of the ecliptic, in degrees, minutes, and seconds: A table of the sun's prosthaphaereses: A table of equations of the sun's ephemerides: A table of the sun's declination: Tables to find the height of the pole in any latitude, from the height of the pole star. These tables are printed in the 2d edition of Edward Wright's treatise, entitled, *Certain Errors in Navigation detected and corrected*; London 1610, 4to.

3. A Description of an Instrumental Table to find the Part Proportional, devised by Mr. Edward Wright. This is subjoined to Napier's table of logarithms, translated into English by Mr. Wright, and after his death published by Briggs, with a preface of his own; London, 1616 and 1618, 12mo.

4. *Logarithmorum Chilias Prima*. Lond. 1617, 8vo.
5. *Lucubrationes et Annotationes in Opera Posthumam J. Neperi*; Edinb. 1619, 4to.

6. *Euclidis Elementorum vi libri priores &c.* Lond. 1620, folio. This was printed without his name to it.

7. A treatise of the North-west Passage to the South Sea &c. By H. B., Lond. 1622, 4to. This was reprinted in Purchas's *Pilgrims*, vol. 3, p. 852.

8. *Arithmetica Logarithmica, &c.* Lond. 1624, folio.
9. *Trigonometria Britannica, &c.* Gouda 1633, folio.

10. Two letters to Archbishop Usher.

11. *Mathematica ab Antiquis minus Cognita*.—This is a summary account of the most observable invention of modern mathematicians, communicated by Mr. Briggs to Dr. George Haweill, and published by him in his *Apologie*; Lond. folio.

Besides these publications, Briggs wrote some other pieces, that have not been printed: as,

(1.) *Commentaries on the Geometry of Peter Ramus*.

(2.) *Duae Epistole ad celeberrimum virum Chr. Sever. Longomontanum*. One of these letters contained some remarks on a treatise of Longomontanus, about squaring the circle; and the other a defence of arithmetical geometry.

(3.) *Animadverses Geometricae*: 4to.

(4.) *De codem Argumento*: 4to.—These two were in the possession of the late Mr. Jones. They both contain a great variety of geometrical propositions, concerning the properties of many figures, with several arithmetical computations, relating to the circle, angular sections, &c.—The two following were also in possession of Mr. Jones:

(5.) A treatise of Common Arithmetic; folio.

(6.) A letter to Mr. Clarke of Gravesend, dated 25 Feb. 1606; with which he sends him the description of a ruler called Bedwell's ruler, with directions how to use it.

BRIGGS (WILLIAM), an eminent physician in the latter part of the 17th century, was born at Norwich, for which town his father was four times member of parliament. He studied at the university of Cambridge; and afterwards travelled into France, where he attended the

lectures of the famous anatomist Vieussens, at Mootpeller. On his return he published his *Ophthalmographia*, in 1676. The year following he was made doctor of medicine at Cambridge, and soon after fellow of the College of Physicians at London. In 1682 he resigned his fellowship to his brother: and the same year his *Theory of Vision* was published by Hooke. The ensuing year he sent to the Royal Society a continuation of that discourse, which was published in their Transactions; and the same year he was appointed physician to St. Thomas's Hospital. In 1684 he communicated to the Royal Society two remarkable cases relating to vision, which were likewise printed in their Transactions; and in 1685 he published a Latin version of his *Theory of Vision*, at the desire of Mr. Newton, afterwards Sir Isaac, then professor of mathematics at Cambridge, with a commendatory epistle from him prefixed to it. He was afterwards made physician in ordinary to King William, and continued in great esteem for his skill in his profession till his death, which happened the 4th of September 1704.

BRIGGS's *Logarithms*, that species of them in which 1 is the logarithm of the ratio of 10 to 1, or the logarithm of 10. See LOGARITHMS.

BROKEN Number, the same as Fraction; which see.

BROKEN Ray, or Ray of Refraction, in Dioptrics, is the line into which an incident ray is refracted or broken, in crossing the second medium.

BROUNCKER, or BROUNKER (WILLIAM), Lord Viscount, of Castle Lyons in Ireland, son of Sir William Brouncker, afterwards made viscount in 1645, was born about the year 1620. He very early discovered a genius for mathematics, in which he afterwards became very eminent. He was made doctor of physic at Oxford, June 23, 1646. In 1657 and 1658, he was engaged in a correspondence by letters on mathematical subjects with Dr. John Wallis, who published them in his *Commercium Epistolicum*, printed 1658, at Oxford. Brounker was one of the nobility and gentry who signed the remarkable declaration concerning king Charles II, published in April 1660.

After the Restoration, Lord Brounker was made chancellor and keeper of the great seal to the queen, also one of the commissioners of the navy, and master of St. Katherine's hospital near the Tower of London. He was one of those great men who first formed the Royal Society, of which he was by the charter appointed the first president in 1662: which office he held, with great advantage to the society, and honour to himself, till the anniversary election, Nov. 30, 1677, when he was succeeded by Sir Joseph Williamson. He died at his house in St. James's street, Westminster, the 5th of April 1684; and was succeeded in his title by his younger brother Harry, who died in January 1687.

Lord Brounker had several papers inserted in the Philosophical Transactions, the chief of which were, 1. Experiments concerning the Recoiling of Guns.—2. A Series for the Quadrature of the Hyperbola; which was the first series of the kind on that subject.—3. Several of his letters to Archbishop Usher were also printed in Usher's Letters; as well as some to Dr. Wallis, in his *Commercium Epistolicum*, above mentioned; particularly an approximation to the circular area by means of continued fractions, of which he was the first inventor.

BROWN (Sir WILLIAM), a noted physician and miscellaneous writer of the 18th century. He first settled

at Lynn in Norfolk, where he published a translation of Dr. Gregory's Elements of Catoptrics and Dioptrics; to which he added, 1. A Method for finding the Foci of all Specula and Lenses universally; as also Magnifying or Lessening a given object by a given Speculum or Lens, in any assigned proportion.—2. A Solution of those Problems which Dr. Gregory has left undemonstrated.—3. A particular account of Microscopes and Telescopes, from Mr. Huygens; with the discoveries made by Catoptrics and Dioptrics.

Having acquired a competence by his profession, he removed to Queen's-square, Ormond-street, London, where he resided till his death, in 1774, at 82 years of age; leaving by his will two prize-medals to be annually contended for by the Cambridge poets.

Sir William Brown it seems was a very facetious man; and a great number of his lively essays, both in prose and verse, were printed and circulated among his friends. The active part taken by him in the contest with the licentiates, in 1768, occasioned his being introduced by Mr. Foote in his Devil upon Two Sticks.—Upon Foote's exact representation of him with his identical wig and coat, tall figure, and glass stiffly applied to his eye, he sent him a complimentary card for having so happily represented him; but as he had forgot the muff, he sent him his own.—This good-natured way of resenting disarmed Foote completely.—He used to frequent the annual ball at the ladies' boarding-school, Queen-square, merely as a neighbour, a good-natured man, and a lover of youthful company. A dignitary of the church being there one day to see his daughter dance, and finding this upright figure stationed in the room, told him he believed he was Hermippus Redivivus who lived anhelitu puellarum.—When he lived at Lynn, a pamphlet was written against him; which he nailed up against his house-door.—At the age of 80, on St. Luke's day 1771, he came to Batson's coffee-house in his laced coat and band, and fringed white gloves, to introduce himself to Mr. Crosby, then lord mayor. A gentleman present observing that he looked very well, he replied, he had neither wife nor debts.

BRUIN (JOHN DE), a respectable mathematician and philosopher, was born at Gorcum in 1620; and having pursued a course of philosophy at Leyden, and prosecuted his studies at Bois-le-Duc and Utrecht, he removed to Leyden, where he taught mathematics. He afterwards became professor at Utrecht, and besides his official duties made dissertations in private, and read lectures on Grotius's treatise *De Jure Belli et Pacis*. He was distinguished by his attachment to experimental philosophy, and by his observations in astronomy. He published dissertations *De vi atrice*; *De corporum gravitate et levitate*; *De cognitione Dei naturali*; *De lucis cause et origine*, &c. He had a dispute with Isaac Vossius, to whom he wrote a letter printed at Amsterdam in 1663, wherein he criticises Vossius's book *De natura et proprietate lucis*; and strenuously maintains the hypothesis of Descartes. He died in 1675, after he had been professor 23 years.

BULLIALD (ISMAEL), an eminent astronomer and mathematician, was born at Laon in the Isle of France in 1605. He travelled in his youth, for the sake of improvement, and gave very early proofs of his astronomical genius. Riccioli styled him, *Astronomus profundus indaginis*. He first published his dissertation entitled, *Philolaus, sive de vero Systemate Mundi*; or his true system

of the world, according to Philolaus, an ancient philosopher and astronomer. Afterward, in the year 1645, he set forth his *Astronomia Philolaica*, grounded upon the hypothesis of the earth's motion, and the elliptical orbit described by the planet's motion about a cone. To which he added tables entitled, *Tabulae Philolaicae*: a work which Riccioli says ought to be attentively read by all students of astronomy.—He considered also the hypothesis or approximation of Bishop Ward, and found it not to agree with the planet Mars; and he showed, in his defence of the Philolaic astronomy against the bishop, that from four observations made by Tycho on the planet Mars, that planet in the first and third quarters of the mean anomaly, was more forward than it ought to be according to Ward's hypothesis; but in the 2d and 4th quadrant of the same, the planet was not so far advanced as that hypothesis required. He therefore set about a correction of the bishop's hypothesis, and made it answer more exactly to the orbits of the planets, which were most eccentric, and introduced what is called, by Street in his *Caroline Tables*, the Variation: these tables were calculated from this correction of Bulliald's, and exceeded all others in exactness that had before been published. This correction is, in the judgment of Dr. Gregory, a very happy one, if it be not set above its due place; and be accounted no more than a correction of an approximation to the true system: for by this means we are enabled to gather the coequate anomaly a priori and that directly from the means, and the observations are well enough answered at the same time; which, in Mercator's opinion, no one had effected before.—It is remarkable that the ellipse which he has chosen for a planet's motion, is such a one as, if cut out of a cone, will have the axis of the cone passing through one of its foci, viz., that next the aphelion.

In 1657 was published his treatise *De Lineis Spiralibus, Exerc. Geom. et Astron.* Paris, 4to. In 1682 came out at Paris, in folio, his large work entitled, *Opus novum ad Arithmeticam Infinitorum*; a work which is a diffuse amplification of Dr. Wallis's *Arithmetic of Infinites*, and which Wallis treats of particularly in the 80th chapter of his *Historical Treatise of Algebra*. He wrote also two *Admonitions to Astronomers*; the first, concerning a new star in the neck of the Whale, appearing at some times, and disappearing at others; the second, concerning a nebulous star in the northern part of Andromeda's girdle, which had not been noticed by any of the ancients. This star also appeared and disappeared by turns. And as these phenomena were new and surprising, he strongly recommended the observing them to all that might be curious in astronomy.

BURGO (LUCAS PACIOLI DE), a celebrated author on arithmetic and algebra, who flourished in the 15th century; and whose works on those subjects were the first that we have in print. See an account of them in the article ALGEBRA.

BURNING, the action of fire on some pabulum or fuel by which its minute parts are put into a violent motion, and some of them, assuming the nature of fire, fly off in orbem, while the rest are dissipated in vapour, or reduced to ashes.

BURNING-Glass, or *Burning-Mirror*, a machine by which the sun's rays are collected into a point; and by that means their force and effect are extremely heightened, so as to burn objects placed in it.

Burning-glasses are of two kinds, convex and concave.

The convex ones are lenses, which, acting according to the laws of refraction, incline the rays of light towards the axis, and unite them in a point or focus. The concave ones are mirrors or reflectors, whether made of polished metal or silvered glass, and which acting by the laws of reflection, throw the rays back into a point or focus before the glass.

The use of burning-glasses, it appears, is very ancient, many of the old authors recording some effects of them. Diodorus Siculus, Lucian, Dion, Zonaras, Galen, Anthemius, Eustatius, Tzetzes, and others, relate that by means of them Archimedes set fire to the Roman fleet at the siege of Syracuse. Tzetzes is so particular in his account of this matter, that his description suggested to Kircher the method by which it was probably accomplished. That author says that "Archimedes set fire to Marcellus's navy by means of a burning-glass composed of small square mirrors, moving every way upon binges; which, when placed in the sun's rays, directed them upon the Roman fleet, so as to reduce it to ashes at the distance of a bow-shot." And the burning power of reflectors is mentioned in Euclid's Optics, theor. 31. Again, Aristophanes, in his comedy of The Clouds, introduces Socrates as examining Strepsiades about a method he had discovered of getting clear of his debts. He replies, that "he thought of making use of a burning-glass which he had hitherto used in kindling his fire; for should they bring a writ against me, I'll immediately place my glass in the sun at some little distance from it, and set it on fire." Pliny and Lactantius have also spoken of glasses that burn by refraction. The former calls them balls or globes of crystal or glass, which being exposed to the sun, transmit a heat sufficient to set fire to cloth, or corrode the dead flesh of those patients who stand in need of caustics; and the latter, after Clemens Alexandrinus, observes that fire may be kindled by interposing glasses filled with water between the sun and the object, so as to transmit the rays to it.

Among the ancients, the most celebrated burning-mirrors were those of Archimedes and Proclus; by the former was burnt the fleet of Marcellus, as above mentioned; and by the latter, the navy of Vitellius, besieging Byzantium, according to Zonaras was burnt to ashes.

Among the moderns, the most remarkable burning-glasses, are those of Magine, of 20 inches diameter; of Settala of Milan, near 42 inches diameter, and which burnt at the distance of 15 feet; of Settala of Villette; of Tschirnhausen, of Buffon, of Trudaine, and of Parker.

Villette, a French artist at Lyons, made a large mirror, which was bought by Tavernier, and presented to the king of Prussia; a second, bought by the king of Denmark; a third, presented to the Royal Academy by the king of France; and a fourth came to England, and was publicly shown. This mirror is 47 inches wide, being a segment of a sphere of 76 inches radius; so that its focus is about 38 inches from the vertex; and its substance is a composition of tin, copper, and tin-glass. Some of its effects were as follow :

						sec.
A silver sixpence melted in	-	-	-	-	-	7½
A George the 1st's halfpenny in	-	-	-	-	-	16
and runs with a hole in	-	-	-	-	-	34
Tin melts in	-	-	-	-	-	3
Cast iron in	-	-	-	-	-	16
Slate in	-	-	-	-	-	3
A fossil shell calcines in	-	-	-	-	-	7

Piece of Pompey's Pillar vitrifies, the black part in 50 sec.
the white part in 54
Copper ore in - - - - - 8
Bone calcines in 4, and vitrifies in - - - - - 33
An emerald melts into a substance like a torquise stone; a diamond weighing 4 grains loses $\frac{1}{2}$ of its weight; the asbestos vitrifies, as all other bodies will do if kept long enough in the focus; but when once vitrified, the mirror can go no further with them. Philos. Trans. vol. 4, p. 198.

Tschirnhausen's reflecting mirrors produced equally surprising effects; as they may be seen described in the Acta Erudit. for 1687, p. 52. And other persons have made very good ones of wood, straw, paper, ice, and other substances capable of taking a proper form and polish.

Every lens, whether convex, plano-convex, or convexo-convex, collects the sun's rays, dispersed over its convexity into a point by refraction; and it is therefore a burning-glass. The most considerable of this kind is that made by Tschirnhausen, and described in the same Acta Erudit. The diameters of his lenses are from 3 to 4 feet, having the focus at the distance of 12 feet, and its diameters an inch and a half. To make the focus more vivid, the rays are collected a second time, by a second lens parallel to the first, and placed at such a distance that the diameter of the cone of rays formed by the first lens is equal to the diameter of the second; so that it receives them all, and the focus is reduced from an inch and a half to half the quantity, and consequently its force is quadrupled. This glass vitrifies tiles, slates, pumice-stones, &c., in a moment. It melts sulphur, pitch, and all rosins, under water; the ashes of vegetables, woods, and other matters, are transmuted into glass, and every thing applied to its focus is either melted, changed into a calx, or into fumes. The author observes that it succeeds best when the matter applied is laid on a hard charcoal well burnt. But though the force of the solar rays be thus found so surprising, yet the rays of the full moon, collected by the same burning-glass, do not show the least increase of heat.

Sir Isaac Newton presented a burning-glass to the Royal Society, consisting of 7 concave glasses, so placed, that all their foci join in one physical point. Each glass is about 11½ inches diameter: six of them are placed contiguous to, and round the 7th, forming a kind of spherical segment, whose subtense is about 34½ inches: the common focus is about 22½ inches distant, and about an inch in diameter. This glass vitrifies brick or tile in 1 second, and melts gold in 30 seconds.

M. Buffon also made a variety of very powerful burning-glasses, both as mirrors and as lenses; but at length concluded with one which is probably of the same nature with that of Archimedes, and consisted of 400 mirrors reflecting their rays all to one point, and with which he could melt lead and tin at the distance of 140 feet; and with others he consumed substances at the distance of 210 feet. See Philos. Trans. vol. 44; Buffon's Hist. Nat. Suppl. vol. 1; or Montucla's Hist. des Math. vol. 1, p. 246.

It appears there is no solid substance capable of resisting the efficacy of modern burning-glasses; though water, &c, are not affected by them at all. Thus, Messrs. Macquer and Baumé have succeeded in melting small portions of platina by means of a concave glass 22 inches diameter, and 28 inches focus, though this metal is not fusible by the strongest fires that can be excited in furnaces, or sustained by any chemical apparatus. Yet it was long since observed, by the Academicians del Cimento, that spirit-of-

wine could not be fired by any burning-glass which they used; and notwithstanding the great improvements these instruments have since received, M. Nollet has not been able, by the most powerful burning-mirrors, to set fire to any inflammable liquors whatever.

However, a large burning-lens, for fusing and vitrifying such substances as resist the fires of furnaces, and especially for the application of heat in *vacuo*, and in certain other circumstances in which heat cannot be applied by other means, has long been desideratum with persons concerned in philosophical experiments: and this it appears is now in a great measure accomplished by Mr. Parker, an ingenious glass-manufacturer in Fleet-street, London. His lens is made of flint-glass, and is 3 feet in diameter; but when fixed in its frame, exposes a surface of 32 inches in the clear; the length of the focus is 6 feet 8 inches, and its diameter one inch. The rays from this large lens are received and transmitted through a smaller, of 13 inches diameter in the clear within the frame, its focal length 29 inches, and diameter of its focus 3-8ths of an inch: so that this second lens increases the power of the former more than 7 times, or as the square of 8 to the square of 3.

From a great number of experiments made with this lens, the following are selected to serve as specimens of its powers :

Substances Fused.				Time in Sec.	Wgt. in Grs.
Scoria of wrought iron	-	-	-	2	12
Common slate	-	-	-	2	10
Silver, pure	-	-	-	3	20

BURNING Zone, or *Torrid Zone*, the space within 23° degrees of the equator, both north and south.

BURROWS (WILLIAM), a writer on the subject of navigation in the 16th century. His "Discourse of the Variation of the Compass or Magnetic Needle," is subjoined to Norman's "Newe Attractive." Burrows had been a famous navigator, having used the sea from 15 years of age, and for his merit was promoted to be controller of the navy by Queen Elizabeth. He shows how to determine the variation several ways, setting down many observations of it, made by an azimuth compass of Norman's invention, but improved by himself. He demonstrates the falsehood of the rules used to find the latitudes by the guard-stars. He particularizes many errors in the then sea-charts, occasioned by the neglect of the variation; adding, "But of these coasts (towards the north) and of the inward parts of the countries of Russia, Muscovia, &c, I have made a perfect plat and description, by myne owne experiance in sundrie viages and travailles, bothe by sea and lande, to and fro in these partes, which I gave to her majestie in anno 1578." And lastly, he justly blames Coignet's instrument, called a Nautical Hemisphere; but speaks too severely against the writers on navigation.

BUSHEL, a measure of capacity for dry goods; as grain, pulse, fruits, &c, containing 4 pecks, or 8 gallons, or $\frac{1}{8}$ of a quarter. By act of parliament, made in 1697, it was ordained that "Every round bushel with a plain and even bottom, being made 18 $\frac{1}{2}$ inches wide throughout, and 8 inches deep, shall be esteemed a legal Winchester bushel, according to the standard in his majesty's exchequer." Now a bushel being thus made will contain 2150.42 cubic inches, and consequently the corn gallon contains only 268 $\frac{1}{2}$ cubic inches.—The weight of a bushel of good corn, or pulse, &c, is commonly accounted to be as follows; viz, of

Wheat	-	-	60 lb. avoirdupois.
Rye	-	-	56
Barley	-	-	50
Beer, or Big.	-	-	44
Oats	-	-	40
Pease	-	-	60
Beans	-	-	60
Potatoes (heaped)	-	-	56

But some experienced persons say that the bushel of good wheat weighs and produces as below; viz,

Bushel of wheat weighs	-	-	63 lb.
Yields of meal	-	-	62
Loss in grinding	-	-	1
Bran in the meal	-	-	6

BUTMENTS, are those supporters, or props, by which the feet of arches or the extremities of bridges are supported; and should be made very strong and firm.

BUTTRESS, is an arch, or a mass of masonry, serving to support the sides of a building, wall, or the like, on the outside. See ARCH, and ARCH-BOUTANT.

C.

C A L

CAISSON, in Architecture, a kind of chest or flat-bottomed vessel, in which the pier of a bridge is built, then sunk to the bottom of the water, and the sides loosened and taken off from the bottom, by a contrivance for that purpose; the bottom of the caisson being left under the pier as a foundation to it. The caisson is kept afloat till the pier is built above the height of low-water mark; and for that purpose, its sides are either made of more than that height at first, or else gradually raised to it as it sinks by the weight of the work, so as always to keep its top above water. Mr. Labelye tells us, that the caissons in which he built some of the piers of Westminster bridge, contained 150 load of fir timber, of 40 cubic feet each, and that it was of more tonnage or capacity than a 40-gun ship of war.

CAISSON, in Military Affairs, is sometimes used for a chest; and in particular for a bomb or shell chest, and is used as a superficial mine, or fourneau. This is done by filling a chest either with gunpowder and loaded shells, or else with shells alone, and burying it in a spot where an enemy, besieging a place, is expected to come, and then firing it by a train to destroy the men.

CALAMUS PASTORALIS, in Music, the Shepherd's Pipe; an ancient musical instrument, the origin of the flute, at first made of straw or reed.

CALCULATION, the act of computing several sums, by adding, subtracting, multiplying, dividing, &c. From calculus, in allusion to the practice of the ancients, who used calculi, or little stones, in making computations, in taking suffrages, and in keeping accounts, &c; as we now use counters, figures, &c. Calculation is more particularly used to signify the computations in astronomy, trigonometry, &c, for making tables of astronomy, of logarithms, ephemerides, finding the times of eclipses, and such like.

CALCULATOR, a person who makes or performs calculations.—It is also the name of a machine constructed by Mr. Ferguson, in the shape of an orrery, for exhibiting the motions of the earth and moon, and resolving a variety of astronomical problems. See his Astron. 4to, p. 265, or 8vo, p. 393.

CALCULATORES were anciently accountants who reckoned their sums by calculi, or little stones, or counters.—In ancient canons too we find a sort of diviners or enchanters, censured under the denomination of Calculatores, probably so called from their calculating nativities.

CALCULUS denotes primarily a small stone, pebble, or counter, used by the ancients in making calculations or computations, taking of suffrages, playing at tables, and the like.

CALCULUS denotes now a certain way of performing mathematical investigations and resolutions. Thus, we say the Arithmetical or Numeral Calculus, the Algebraical Calculus, the Differential Calculus, the Exponential Calculus, the Fluxional Calculus, the Integral Calculus, the Literal or Symbolical Calculus, &c; for which, see each respective word.

Arithmetical or Numeral CALCULUS, is the method of

performing arithmetical computations by numbers. See ARITHMETIC, and NUMBER.

Algebraical, Literal, or Symbolical CALCULUS, is the method of performing algebraical calculations by letters or other symbols. See ALGEBRA.

Differential CALCULUS, is the arithmetic of the indefinitely small differences of variable quantities; a mode of computation much used by foreign mathematicians, and introduced by Leibnitz, as similar to Newton's method of Fluxions. See DIFFERENTIAL &c.

Exponential CALCULUS, is the applying the fluxional or differential methods to exponential quantities; such as a^x , or x^x , or ay^x , &c. See EXPONENTIAL.

Fluxional CALCULUS, is the method of fluxions, invented by Newton. See FLUXIONS.

Integral CALCULUS, or Summatorius, is a method of integrating, or summing up differential quantities; and is similar to the finding of fluents. See INTEGRAL and FLUENT.

CALCULUS Literalis, or Literal Calculus, is the same with algebra, or specious arithmetic, so called from its using the letters of the alphabet; in contradistinction from numeral arithmetic, in which figures are used.

CALENDAR, or KALENDAR, a distribution of time as accommodated to the uses of life; or an almanac, or table, containing the order of days, weeks, months, feasts, &c, occurring in the course of the year: it is so called from the word Calendæ, which among the Romans denoted the first days of every month, and anciently was written in large characters at the head of each month. See ALMANAC, CALENDS, MONTH, TIME, YEAR, &c.

In calendars, the days were originally divided into octoades, or eights; but afterwards, in imitation of the Jews and Orientals, they were divided into hebdomades, or sevens, for what we now call a week: which custom, Scaliger observes, was not in use among the Romans till after the time of Theodosius.

Divers calendars are established in different countries, according to the different forms of the year, and distributions of time: as the Persian, the Roman, the Jewish, the Julian, the Gregorian, &c, calendars.—The ancient Roman calendar is given by Ricciolus, Struvius, Danet, and others; in which we perceive the order and number of the Roman holy-days and work-days.—The Jewish calendar was fixed by Rabbi Hillel, about the year 360; from which time the days of their year may be reduced to those of the Julian calendar.—The three Christian calendars are given by Wolfius in his Elements of Chronology; as also the Jewish and Mohamedan calendars. Other writers on the calendars are Vieta, Clavius, Scaliger, Blondel, &c.

The Roman CALENDAR was first formed by Romulus, who distributed time into several periods for the use of his followers and people under his command. He divided the year into 10 months, of 304 days; beginning on the first of March, and ending with December.

Numa reformed the calendar of Romulus. He added the months of January and February, making it to com-

mence on the first of January, and to consist of 355 days. But as this was evidently deficient of the true year, he ordered an intercalation of 45 days to be made every 4 years, in this manner, viz., Every 2 years an additional month of 22 days, between February and March; and at the end of each two years more, another month of 23 days; the month thus interposed, being called Marcedonius, or the intercalary February.

Julius Caesar, with the aid of Sosigenes, a celebrated astronomer of those times, further reformed the Roman calendar, whence arose the Julian calendar, and the Julian or old style. Finding that the sun performed his annual course in 365 days and a quarter nearly, he divided the year into 365 days, but every 4th year 366 days, adding a day to the 23d of February, which being the 6th of the calends, and thus reckoned twice, gave occasion to the name Bissextile, or what we also call leap-year.

This calendar was further reformed by order of the pope, Gregory XIII; from whence arose the term Gregorian calendar and style, or what is now called the new style, which is now observed by almost all nations in Europe. The year of Julius was too long by nearly 11 minutes, which amounts to about 3 days in 400 years; the pope therefore, by the advice of Clavius and Ciconius, ordained that there should be omitted a day in every 3 centuries out of 4; so that every century, which would otherwise be a bissextile year, is made to be only a common year, excepting only such centuries as are exactly divisible by 4, which happens once in 4 centuries. See *BISSEXTILE*. This reformation of the calendar, or the new style, as we call it, commenced in the countries under the popish influence, on the 4th of October 1582, when 10 days were omitted at once, which had been over-run since the time of the council of Nice, in the year 325, by the surplus of 11 minutes each year. But in England it only commenced in 1752, when 11 days were omitted at once, the 3d of September being accounted the 14th that year; as the surplus minutes had then amounted to 11 days. And now, since the year 1800, another day has been added on account of the odd minutes; so that now our new style differs from the old by 12 days.

Julian Christian CALENDAR, is that in which the days of the week are determined by the letters A, B, C, D, E, F, G, by means of the solar cycle; and the new and full moons, particularly the paschal full moon, with the feast of Easter, and the other moveable feasts depending on it, by means of golden numbers, or lunar cycles, rightly disposed through the Julian year. See *CYCLE*, and *GOLDEN NUMBER*.

In this calendar, it is supposed that the vernal equinox is fixed to the 21st day of March; and that the golden numbers, or cycles of 19 years, constantly indicate the places of the new and full moons; though both are erroneous; and from hence arose a great irregularity in the time of Easter.

Gregorian CALENDAR, is that which, by means of epacts, rightly disposed through the several months, determines the new and full moons, with the time of Easter, and the moveable feasts depending on it, in the Gregorian year. This differs therefore from the Julian calendar, both in the form of the year, and in as much as epacts are substituted instead of golden numbers. See *EPACT*.

Though the Gregorian calendar be more accurate than the Julian, yet it is not without imperfections, as Scaliger and Calvisius have fully shown; nor does it appear pos-

sible to devise any one that shall be quite perfect. Yet the Reformed Calendar, and that which is ordered to be observed in England, by act of parliament made the 24th of George II, come very near to the point of accuracy: For, by that act it is ordered that "Easter-day, on which the rest depend, is always the first Sunday after the full moon, which happens upon, or next after the 21st day of March; and if the full-moon happens on a Sunday, Easter-day is the Sunday after."

Reformed, or Corrected, CALENDAR is that which, rejecting all the apparatus of golden numbers, epacts, and dominical letters, determines the equinox, and the paschal full moon, with the moveable feasts depending on it, by computation from astronomical tables. This calendar was introduced among the protestant states of Germany in the year 1700, when 11 days were omitted in the month of February, to make the corrected style agree with the Gregorian. This alteration in the form of the year, they admitted for a time; in expectation that, the true quantity of the tropical year being at length more accurately determined by observation, the Romanists would agree with them on some more convenient intercalation.

French New CALENDAR, is quite of a different form of calendar from all others. It commenced in France on the 22d of September 1792, soon after the change of government. At the time of printing this (viz., in July 1794), it does not certainly appear whether this new calendar will be made permanent or not; but merely as a curiosity in the science of chronology, a very brief notice of it may here be added, as follows.

The year, in this calendar, commences at midnight the beginning of that day in which fall the true autumnal equinox for the observatory of Paris. The year is divided into 12 equal months, of 30 days each; after which 5 supplementary days are added, to complete the 365 days of the ordinary year: these 5 days do not belong to any month. Each month is divided into three decades of 10 days each; distinguished by 1st, 2d, and 3d decade. All these are named according to the order of the natural numbers, viz., the 1st, 2d, 3d, &c, month, or day of the decade, or of the supplementary days. The years which receive an intercalary day, when the position of the equinox requires it, which we call embolismic or bissextile, they call olympic; and the period of four years, ending with an olympic year, is called an olympiad; the intercalary day being placed after the ordinary five supplementary days, and making the last day of the olympic year. Each day, from midnight to midnight, is divided into 10 parts, each part into 10 others, and so on to the last measurable portion of time.

In this calendar the months and days have new names. The first three months of the year, of which the autumn is composed, take their etymology, the first from the vintage which takes place from September to October, and is called Vendemaire; the second, Brumaire, from the mists and low fogs, which show as it were the transmutation of nature from October to November: the third, Frimaire, from the various colds which are generally felt from November to December. The three winter months take their etymology, the first, Nivose, from the snow which whitens the earth from December to January; the second, Pluviose, from the rains which usually fall in greater abundance from January to February; the third, Ventose, from the wind which dries the earth from February to March. The three spring months take their etymology, the first, Ger-

inal, from the fermentation and developement of the sap from March to April; the second, Floreal, from the blowing of the flowers from April to May; the third, Prairial, from the smiling fecundity of the meadow crops from May to June. Lastly, the three summer months take their etymology, the first, Messidor, from the appearance of the waving ears of corn and the golden harvests which cover the fields from June to July; the second, Thermidor, from the heat, at once solar and terrestrial, which inflames the air from July to August; the third, Fructidor, from the fruits gilt and ripened by the sun from August to September. Thus, the whole 12 months are,

AUTUMN.	SPRING.
Vendemaire	Germinal
Brumaire	Floreal
Frimaire.	Prairial.
WINTER.	SUMMER.
Nivose	Messidor
Pluviose	Thermidor
Ventose.	Fructidor.

From these denominations it follows, that by the mere pronunciation of the name of the month, every one readily perceives three things and all their relations, viz, the kind of season, the temperature, and the state of vegetation: for instance, in the word *germinal*, his imagination will easily conceive, by the termination of the word, that the spring commences; by the construction of the word, that the elementary agents are busied; and by the signification of the word, that the buds unfold themselves.

As to the names of the days of the week, or decade of 10 days each, which they have adopted instead of seven, as these bear the stamp of judicial astrology and heathen mythology, they are simply called from the first ten numbers; thus,

Primidi	Sextidi
Duodi	Septidi
Tridi	Octidi
Quartidi	Nonidi
Quintidi	Decadi.

In the almanac, or annual calendar, instead of the multitude of saints, one for each day in the year, as in the popish calendars, they annex to every day the name of some animal, or utensil, or work, or fruit, or flower, or vegetable, &c, appropriate and most proper to the times. This calendar however was changed for the old one again, with the change of the form of government. For the calendars of the Greeks, Egyptians, Jews, Syrians, Persians, Mahomedans, Ethiopians, &c, see the article YEAR.

CALENDAR Months, the solar months as they stand in the calendar, viz, January 31 days, &c. The number of days in each month may be suggested to the memory by the following canon:

"Thirty days hath September,
April, June, and November;
February has twenty-eight alone,
And all the rest have thirty-one."

Astronomical CALENDAR, an instrument engraven upon copper-plates, printed on paper, and pasted on board, with a brass slider which carries a hair, and shows by inspection the sun's meridian altitude, right ascension, declination, rising, setting, amplitude, &c, to a greater exactness than can be shown by the common globes.

CALENDIS, *Calenda*, in the Roman Chronology, denoted the first days of each month; being so named from *nauis*, (caleo) I call, or proclaim; because that, before the

publication of the Roman Fasti, and counting their months by the motion of the moon, a priest was appointed to observe the first appearance of the new moon; who, having seen her, gave notice to the president of the sacrifices to offer one; and calling the people together, he proclaimed unto them how they should reckon the days until the nones; pronouncing the word *Caleo* 5 times if the nones should happen on the 5th day, or seven times if they happened on the 7th day of the month.

The calends were reckoned backwards, or in a retrograde order: thus, for example, the first of May being the calends of May, the last or 30th day of April was the pridie calendarum, or 2d of the calends of May; the 29th of April, the 3d of the calends, or before the calends: and so back to the 15th, where the ides commence; which are likewise numbered backwards to the 5th, where the nones begin; and also reckoned after the same manner to the first day of the month, which is the calends of April.

Hence comes this rule to find the day of the calends answering to any day of the month, viz, Consider how many days of the month are yet remaining after the day proposed, and to that number add 2, for the number of or from the calends. For example, suppose it were the 23d day of April, it would then be the 9th of the calends of May: for April containing 30 days, from which 23 being taken, there remains 7; to which 2 being added, makes the sum 9. And the reason for this addition of the constant number 2, is because the last day of the month is called the 2d of the calends of the month following.

CALIBER, or **CALIPER**, is the thickness or diameter of a round body, particularly the bore or width of a piece of ordnance, or that of its ball.

CALIBER Compasses, or **CALIPER Compasses**, or simple **CALIPERS**, a sort of compasses made with bowed or arched legs, the better to take the diameter of any round body; as the diameters of balls, or the bores of guns; or the diameter, and even the length of casks, and such like. The best sort of calipers usually contain the following articles, viz, 1st, the measure of convex diameters in inches &c; 2d, of concave diameters; 3d, the weight of iron shot of given diameters; 4th, the weight of iron shot for given gun bores; 5th, the degrees of a semicircle; 6th, the proportion of troy and avoirdupois weight; 7th, the proportion of English and French feet and pounds weight; 8th, factors used in circular and spherical figures; 9th, tables of the specific gravities and weights of bodies; 10th, tables of the quantity of powder necessary for the proof and service of brass and iron guns; 11th, rules for computing the number of shot or shells in a complete pile; 12th, rules for the fall or descent of heavy bodies; 13th, rules for the raising of water; 14th, rules for firing artillery and mortars; 15th, a line of inches; 16th, logarithmic scales of numbers, sines, versed sines, and tangents; 17th, a sectorial line of equal parts, or the line of lines; 18th, a sectorial line of planes and superficies; and 19th, a sectorial line of solids.

CALIPPIC Period, in Chronology, a period of 76 years, continually recurring; at every repetition of which, it was supposed, by its inventor Calippus, an Athenian astronomer, that the mean new and full moons would always return to the same day and hour.

About a century before, the golden number or cycle of 19 years had been invented by Meton, which Calippus finding to contain 19 of Nabonassar's year, 4 days and $\frac{2}{3}$, to avoid fractions he quadrupled it, and so produced

his period of 76 years, or 4 times 19; after which he supposed all the lunations &c would regularly return to the same hour. But neither is this exact, as it brings them too late by a whole day in 225 years.

CALORIC, in the new Chemical Nomenclature, is that supposed material substance which possesses the power of exciting the feeling of heat in the animal body; or it is the matter and the cause of heat.

The general properties of caloric are the following: If it be considered as material, it must be a substance of extreme subtlety and tenuity, entirely imponderable by human instruments, derived immediately from the sun together with light, and like light obeying certain and similar laws of reflection and refraction, and also elicited by combustion and by various other instances of chemical action, percussion or collision, friction, the electric spark, galvanism, &c: when uncombined, moving with immense velocity in every direction, and constantly tending to an equilibrium; penetrating all bodies in nature with more or less facility, and thereby enlarging their dimensions, without increasing their weight: when combined, probably entering into chemical union with other bodies, and thereby constituting the different states of liquid, vapour, or gas: and lastly, when applied suddenly to the animal body, occasioning the sensations of warmth, heat, or, in greater intensity, burning. See the articles LIGHT and HEAT.

Caloric, then, is a word used to denote that substance by which the phenomena of heat are produced; and the same as was formerly termed *igneous fluid*, *matter of heat*, and other analogous denominations. There are perhaps few subjects respecting which a more remarkable versatility of general opinion has been evinced, than with regard to the existence or non-existence of this principle. Are the physical effects of heat produced by the operation of a material fluid, *sui generis*? or is heat merely an affection, consisting in internal vibrations and collisions of its particles, or in some other mode of corpuscular action, of which we are ignorant, and is there consequently no such thing as caloric? These are the questions that have divided the opinions of many of the ablest philosophers of both ancient and modern times; but though different opinions still prevail on this subject, yet the former of these hypotheses seems to be most generally received. Among the ancients who supposed the materiality of heat, may be reckoned Zeno and Cicero: the latter, in his book *De Natura Deorum*, says expressly, that heat is combined with water, as its liquefaction sufficiently proves; and that it cannot freeze nor congeal into snow or hoar-frost, without suffering that heat to escape, &c, &c: which is very nearly the idea that we have of it at the present day; and indeed this appears to have been the most prevailing opinion till the time of Lord Bacon, who, in his work *De Forma Calidi*, considers heat as the effect of an intestine motion, or mutual collision of the particles of the body heated; an expansive undulatory motion in the minute particles of the body, by which they tend with some rapidity towards the circumference, and at the same time incline a little upwards; which idea was also with some modifications adopted by Descartes, Newton, Boyle, and the other mechanical philosophers of the succeeding age. The general opinion however among chemists, was still in favour of the materiality of heat; and as chemistry became more generally known, so this opinion gained strength, till Count Rumford by some experiments seemed to show, that heat was imponderable, and capable of being

produced, ad infinitum, from a finite quantity of matter, which again threw some doubt on this question; and though these results appear, in some degree, to have been confuted by subsequent experiments, yet is the matter at present undecided, and will probably always be involved in some obscurity. We cannot here enter into the merits of the particular arguments that have been advanced on both sides of this intricate and interesting inquiry; but we shall enumerate a few of the principal experiments that have been made on this subject, and shall then leave the reader to draw his own conclusion, as to the materiality or immateriality of heat, or the cause of heat; or, in other words, of the existence or non-existence of that substance which is defined by the term Caloric.

It is known, that when water freezes, a portion of heat is given out by it during the congelation, which is so considerable, that if we were to conceive it to be transmitted to, and imbibed by an equal quantity of water at the temperature of 32° of Fahrenheit's thermometer, the latter would be heated to no less than 140°, or to 172°; if therefore heat were a ponderable substance, it might be imagined that a given quantity of water would become lighter when frozen in a vessel hermetically sealed. This circumstance therefore induced some philosophers to ascertain, if possible, the ponderability of caloric, and thus to decide the question on which so many opinions had been formed. Of the experiments made for this purpose, that of Dr. Fordyce seems to have been conducted with the greatest caution. He took a glass globe, three inches in diameter, with a short neck, and weighing 451 grains; poured into it 1700 grains of water from the New River, London, and then sealed it hermetically. The whole of which then weighed $2150\frac{1}{2}$ grains, at the temperature of 32°: this was then put for 20 minutes into a freezing mixture of snow and salt, till some of it was frozen, and was then taken out, and wiped perfectly dry with a linen cloth, and next with a clean dry piece of washed leather; and being then immediately weighed, it was found to be $\frac{1}{6}$ th of a grain heavier than before: this was repeated five times, at each time more of the water was frozen, and more weight gained; and when the whole was frozen, it was found to have gained $\frac{1}{6}$ ths of a grain; but the temperature of the globe, and contained ice, by having been kept in the frozen mixture, had been reduced to 12° of Fahrenheit's thermometer: and on allowing it to rise to 32°, it was found to weigh $\frac{1}{6}$ th of a grain more than when the water was fluid. The beam in this experiment was so adjusted that it would mark $\frac{1}{6000}$ of a grain.

By this result therefore it appears that water by freezing, an operation in which it evolves caloric, becomes heavier, and that of course the addition of caloric to a body renders it absolutely lighter; which if admitted goes to prove, that caloric counteracts the effect of gravitation, as it does that of contiguous attraction or affinity. This experiment was repeated by Morveau and Chaussier, and with the same result, the water being heavier after it had been frozen in glass vessels hermetically sealed, than it was before when in its fluid state.

This subject soon attracted the attention of Lavoisier; and his experiments, which were published in the *Memoirs of the French Academy*, led him to conclude that the weight of bodies is not at all altered by heating or cooling them, and consequently that caloric produces no sensible change in the weight of bodies. Count Rumford also made similar experiments, and was at first led to the same

conclusion as Dr. Fordyce; but afterwards, by varying the experiments, he had reason to suppose that he had been mistaken in the first instance, and he finally came to the same conclusion as Lavoisier. Hence then we may conclude from these experiments, and others of a similar nature which have been made on this subject, that if caloric be possessed of weight, it exists at least in such a state of rarity, that its gravity cannot be ascertained by experiment. But Count Rumford went still further, and endeavoured to prove that an inexhaustible supply of heat may be produced from a finite quantity of matter; and that therefore heat must be an effect arising from some species of corpuscular action among the constituent particles of the body, agreeably to the notions of Bacon. This experiment was conducted in the following manner. The Count caused a cylinder of brass to be turned $7\frac{1}{2}$ inches in diameter, and 9 $\frac{1}{8}$ inches long, which was bored like a cannon with a caliber 3 $\frac{1}{2}$ inches in diameter, and 7 $\frac{1}{2}$ inches deep; so that the bottom was 2 $\frac{1}{2}$ inches in thickness. The hollow cylinder contained 385 $\frac{1}{2}$ cubic inches of brass, and weighed 113-13lbs avoirdupois. By means of the engine used for boring cannon in the arsenal of Munich, a blunt borer, or flat piece of hardened steel, 4 inches long, 0-63 inch thick, and 3 $\frac{1}{2}$ inches wide, was kept with one of its extremities, whose area was about 2 $\frac{1}{2}$ square inches, pressed against the bottom of this hollow cylinder on the inside, with a force of about 10,000lbs avoirdupois, while the latter was turned about its axis, with a velocity of 32 revolutions in a minute. In one experiment, the cylinder was covered on the outside with a coating of thick flannel, to prevent the access of heat from the atmosphere; and in another, the borer was made to work through a collar of leathers, so as to prevent access of air also to the interior of the bore; and in a third, the whole cylinder was immersed in water, the borer still working through a collar of leathers, so as to prevent the access of the water to the interior of the bore; again, in a fourth, the collar of leathers was removed, and the water had access to the bottom of the interior of the bore where the friction took place. The result was, that in all these cases heat was generated by the friction in sufficient quantity to cause about 26 $\frac{1}{2}$ lbs of ice-cold water to boil in two hours and a half; or at about the same rate as that at which it would have been produced by 9 large wax candles. The capacity of brass for heat, or its power of producing it by friction, did not appear to be diminished, and it seemed that this generation of heat would have gone on for ever, if the friction had been continued, or that the source of it was inexhaustible. Now any thing which an insulated body, or a system of bodies, can continue to supply without limitation, cannot possibly be a material substance; and hence the conclusion was, that heat must be an effect arising from some species of corpuscular action among the constituent particles of the body.

Some other experiments of M. Pictet, Mr. Davy, and other celebrated chemists, seem to be in favour of the conclusions drawn by Count Rumford from those above stated; but there are others, that appear to contradict this principle, some of which were made by the Count himself.

If heat arise only from the corpuscular motion of the particles of the body, it would follow that no heat could be produced, but in those cases where motion could be communicated; whence again heat could not be derived through a vacuum. But Count Rumford, by a very satis-

factory experiment, has shown that heat may be communicated through a Torricellian vacuum, in which there could be nothing to communicate or propagate motion; for though such a vacuum may be not quite complete, yet the matter of it must be in such a state of rarity, as to prevent us from supposing for a moment, that it is capable of exciting motion in the particles of the body placed in it; and consequently, that the conclusion drawn from the boring experiment was inaccurate: and a recent discovery made by Dr. Herschel, has at last nearly put an end to the dispute; by demonstrating that caloric is not a property of matter, but a peculiar substance; or at least that we have the same reason for considering it as a substance, as we have for believing light to be material.

Dr. Herschel had been employed in making observations on the sun by means of telescopes; and to prevent the inconvenience arising from the heat, he used coloured glasses; but these glasses, when they were deep enough coloured to intercept the light, very soon cracked and broke to pieces; which circumstance induced him to examine the heating power of the different coloured rays. He therefore made each of them in its turn fall upon the bulb of a thermometer, near which two other thermometers were placed to serve as standard; and the number of degrees that the thermometer exposed to the coloured ray rose above the other two thermometers, indicated the heating power of that ray. He thus found, that the most refrangible rays have the least heating power; this power gradually increasing as the refrangibility diminishes. The heating power of the Violet = 16 green, violet, and red rays, as determined Green = 22 $\frac{1}{4}$ by these experiments are expressed by Red = 55 Dr. Herschel, by the annexed numbers.

It struck Dr. Herschel as very remarkable, that the illuminating power and the heating power of the solar rays should follow such different laws: the first existing in greatest perfection in the middle of the spectrum, and diminishing as we approach either extremity; but the second constantly increasing from the violet end, and being greatest at the red end. This led him to suspect, that probably the heating power did not stop at the termination of the visible spectrum, but is continued beyond it; he therefore placed the thermometer completely without the boundary of the red ray, but still in the line of the spectrum; and it rose still higher than when exposed to the red ray: and on shifting the thermometer still further it continued to rise; the rise not reaching its maximum till the thermometer was half an inch beyond the visible spectrum: when shifted still further, it sank a little, but the power of heating did not cease at the distance of an inch and a half from the real ray.

These experiments were afterwards repeated and fully confirmed by Sir Henry Englefield, in the presence of some very good judges. The apparatus was very different from that of Dr. Herschel, being contrived on purpose to obviate certain objections which had been made to the conclusion drawn by that celebrated philosopher; and the bulbs of the thermometers were mostly blackened. The following are the results of these experiments.

Thermometer in the blue ray	rose in 3 $\frac{1}{2}$	from 55°	to 56°
green	- - 3	-	54 - 58
yellow	- - 3	-	56 - 62
full red	- 2 $\frac{1}{2}$	-	56 - 72
confines of red	2 $\frac{1}{2}$	-	58 - 73 $\frac{1}{2}$
beyond the visible light	2 $\frac{1}{2}$	-	61 - 79

The thermometer with its bulb blackened, rose much more when placed in the same circumstances, than the thermometers whose bulb was either naked, or whitened with paint; as is shown in the following table:

Red ray	{ black thermometer in 3 ^m from 58° to 61°
	{ white thermometer 3 - 55 - 58
Dark	{ black thermometer 3 - 59 - 64
	{ white thermometer 3 - 58 - 58½
Confines of red	{ black thermometer 3 - 59 - 71
	{ white thermometer 3 - 57½ 60½

Both Dr. Herschel and Sir H. Englefield take notice of a faint blush of red, of a semi-oval form, visible when the rays beyond the end of the spectrum were collected by a lens.

From these experiments it follows, that there are rays emitted from the sun which produce heat, but have not the power of illuminating; and that these are the rays that produce the greatest quantity of heat: and consequently calorific is emitted from the sun in rays, and the rays of calorific are not the same with the rays of light.

We have thus enumerated many of the principal experiments that have been made, in order to prove the materiality or immateriality of heat; and without insisting further on this subject, on which probably the present state of knowledge is insufficient for forming a decided opinion. It seems however that, under all the circumstances attending this inquiry, we ought rather to consider it as a material substance; because of the two theories, that which supposes it to be so is by far the most intelligible, the most agreeable to the analogy of nature, and the least exceptionable; and we shall accordingly regard it as an elastic fluid, *sui generis*, capable of pervading, with various degrees of facility, all the solid bodies with which we are acquainted, and of being imbibed and retained by them in different proportions, according to their respective degrees of specific attraction, or capacity for it.

It will easily be conceived, that from the elasticity and power of pervading other substances, which we have attributed to this fluid, it must necessarily follow that when a body is by any means charged with a larger quantity of it than is proportional to its mass and capacity, when compared with those of other bodies in its vicinity; the surplus will be communicated to those other bodies, until the density of the fluid in every body in the system becomes equal; in like manner as a quantity of air thrown into one of a number of vessels communicating with each other, will pass from it to the others, until it becomes distributed among them all, in proportion to their respective capacities; or till it becomes of equal density in them all: and this state of density or compression of the calorific is called its temperature.

The celerity and facility with which this fluid pervades different substances, are however extremely various, as may be shown by the following experiment. Take a small cylindrical earthen or wooden vessel, between three and four inches in diameter, and insert into it, through holes drilled in its bottom for that purpose, several wires about $\frac{1}{8}$ th of an inch in diameter, and 6 or 7 inches long, of equal size in every respect, but of different metals, as gold, silver, copper, iron, brass, and zinc; and also two small rods, one of glass and the other of wood, of equal dimensions with the wire; so that they may each of them project about $\frac{1}{2}$ an inch on the inside of the vessel; the other parts being on the outside, and forming a kind of stand for it. Dip a portion of the lower extremities of

these wires into melted wax, so that they may become equally coated with it; and when the wax has cooled, fill the vessel with a heated fluid, as boiling water, or melted lead, and observe the intervals between the time of filling it, and the melting of the wax; which intervals, will indicate the relative conducting power of the substances.

We shall now conclude this article by a slight investigation of the effects arising from the condensation or rarefaction of this fluid in bodies: by the former their temperature is elevated, or they are heated; and by the latter it is depressed, or they become cooled.

In our investigation of the most universal operations in nature, we generally find that the more immediate instruments employed for the production of the effects which we perceive, are two counteracting powers, by whose co-operation, and mutual counterpoise, the necessary equilibrium is preserved, and the purposes of their creation effected, with greater regularity than would probably result from the employment of a single agent. Thus, gravity is, as we know, counteracted by inertia; and the effects of cohesion, a no less universal principle than gravity, are in like manner restrained and modified by the agency of calorific: and as without inertia, all the celestial bodies would be drawn together into some one part of extended space; so without heat, all the matter in the universe would become a congealed and concrete mass; and fluidity and organization, vegetation, and life, would have no existence. Solids become first expanded, and then liquified, by its influence, and liquids assume the aëroform state. It is essential to the idea of a solid body, that it should in a certain degree resist both compression and dilatation; that is, that its particles should repel each other when brought nearer together, and attract each other when further separated, within certain limits; and it is incontrovertible that they can only remain in a quiescent state, by the equilibrium of these opposite forces. The latter of these constitutes cohesion, and the existence of the former is probably attributable to the substance of which we are now speaking. But be this as it may, it is at least a fact, that the repulsive energies of these corpuscles are increased, and the sphere of action enlarged by its influence, for the body becomes expanded; that is, this equilibrium no longer takes place, unless its molecules are removed further from each other than when it was at a lower temperature. Elevate its temperature still further, and the body fuses; that is, the attractive power of its particles becomes annihilated, or wholly counteracted, and they are only kept together, like a quantity of shot, by the action of gravity, operating independently on each. Increase still the action of heat on the body, and the sphere of repulsion of its particles, or the distance to which this power operates, again becomes much further extended, perhaps infinitely so, and is therefore sufficient to overpower the action of gravity, and the body becomes resolved into an elastic fluid. We know of no power that is capable of resisting this universal solvent: gold itself may be expanded into vapour by the action of heat; and as these effects are always producible by the same cause, so is it at least probable, that the converse of this is also true; that whenever a substance is formed in a state of fluidity, it is attributable solely to this cause, and that the abstraction of the calorific, by which it is held in solution, would again reduce it to a solid. Mercury is, we know, capable of congelation; and the atmosphere itself would probably become a concrete body, if we could deprive it of all, or the greater part of its heat.

Hence then we arrive at a very distinctive and appropriate definition of caloric; that it is that substance, or affection of matter, which is the cause of fluidity, in all or the greater part of the bodies that we meet with in that state.

For a fuller and more detailed account of caloric and its various properties, see Murray's or Thomson's Chemistry; and for the ancient opinions on this subject see *Heat*.

CAMBER-BEAM, a piece of timber cut arch-wise, or with an obtuse angle in the middle. They are commonly used in platforms, as for church-roofs, and other occasions where long timbers are wanted to lie at a small slope. A camber-beam is much stronger than another of the same dimensions; for being laid with the hollow side downwards, and having good butments at the ends, they serve for a kind of arch.

CAMELEON, one of the constellations of the southern hemisphere, near the south pole, and invisible in our latitude. There are ten stars marked in this constellation in Sharpe's catalogue.

CAMELOPARDALUS, a new constellation of the northern hemisphere, formed by Hevelius, consisting of 32 stars first observed by him. It is situated between Cepheus, Cassiopeia, Perseus, the Two Bears, and Draco; and it contains 58 stars in the British catalogue.

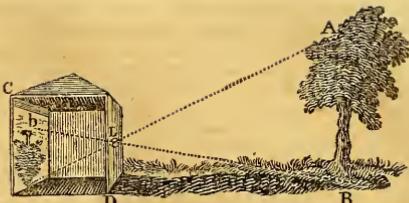

CAMERA *Hæolia*, a name given by Kircher to a contrivance for blowing the fire, for the fusion of ores, without bellows. This is effected by means of water falling through a funnel into a close vessel, which sends from it so much air or vapour, as continually blows the fire. See Hooke's *Philos. Coll.* No. 3, pa. 80.

CAMERA *Lucida*, a contrivance of Dr. Hooke to make the image of any thing appear on a wall in a light room, either by day or night. See *Philos. Trans.* No. 38, pa. 741. Another camera lucida has lately been introduced by William Hyde Wollaston, M. D. secretary of the Royal Society.

CAMERA *Obscura*, or *Dark Chamber*, an optical machine or apparatus, representing an artificial eye, by which the images of external objects, received through a double convex glass, are shown distinctly, and in their native colours, on a white ground placed within the machine, in the focus of the glass. The first invention of the camera obscura is ascribed to John Baptista Porta. See his *Magna Naturalis*, lib. 17, cap. 6, where he largely describes the effects of it. See also the end of Gravesande's Perspective, and other optical writers, for the construction and uses of various sorts of camera obscuras.

This machine serves for many useful and entertaining purposes. For example, it is very useful in explaining the nature of vision, representing a kind of artificial eye: it exhibits very diverting spectacles; showing images perfectly like their objects, clothed in their natural colours, but more intense and vivid, and at the same time accompanied with all their motions; an advantage which no art can imitate: and by this instrument, a person unacquainted with painting, or drawing, may delineate objects with the greatest accuracy of drawing or colouring.

Theory of the Camera Obscura. The theory and principle of this instrument may be thus explained. If any object *AB* radiate through a small aperture *L*, upon a white ground opposite to it, within a darkened room, or box, &c; the image of the object will be painted on that ground in an inverted position. For, by the smallness of the aperture, the rays from the object will cross each other

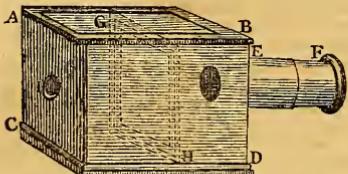

there, the image of the point *a* being at *b*, and that of *b* at *a*; so that the whole object *AB* will appear inverted, as at *ab*. And as the corresponding rays make equal angles on both sides of the aperture, if the ground be parallel to the object, their heights will be to each other directly as their distances from the aperture.

Construction of a Camera Obscura, in which the images of external objects shall be represented distinctly, and in their genuine colours, either in an inverted or an erect situation. 1st, Darken a chamber that has one of its windows looking towards a place containing various objects to be viewed, leaving only a small aperture open in one shutter. 2d, In this aperture fit a proper lens, either plano-convex, or convex on both sides; the convexity forming a small portion of a large sphere. But note, that if the aperture be made very small, as of the size of a pea, the objects will be represented even without any lens at all. 3d, At a proper distance, to be determined by trials, stretch a paper or white cloth, unless there be a white wall at that distance, to receive the images of the objects: or the best way is to have some plaster of Paris cast on a convex mould, so as to form a smooth concave surface, and of a curvature and size adapted to the lens, to be placed occasionally at the proper distance. 4th, If it be desired to have the objects appear erect, instead of inverted, this may be done either by placing a concave lens between the centre and the focus of the first lens; or by reflecting the image from a plane speculum inclined to the horizon in an angle of 45 degrees; or by having two lenses included in a draw-tube, instead of one.

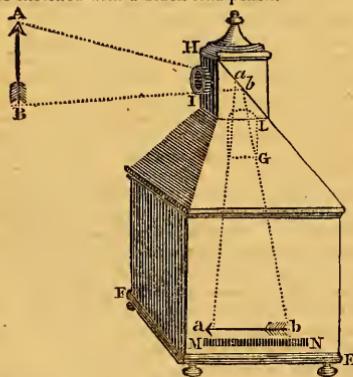

That the images be clear and distinct, it is necessary that the objects be illuminated by the sun's light shining upon them from the opposite quarter: so that, in a western prospect, the images will be best seen in a forenoon, an eastern prospect the afternoon, and a northern prospect about noon; a southern aspect is the least eligible of any. But the best way of any is, if the lens be fixed in a proper frame, on the top of a building, and made to move easily round in all directions, by a handle extended to the person who manages the instrument; the images being then thrown down into a dark room immediately below it, on a horizontal plaster of Paris ground little concave: for thus a view of all the objects quite around may easily be taken in the space of a few minutes; as in the case of the excellent camera obscura placed on the top of the Royal Observatory at Greenwich.

The objects will be seen brighter, if the spectator first wait a few minutes in the dark. Care should also be taken, that no light escape through any chinks; and that the ground be not too much illuminated. It may further be observed, that the greater distance there is between the aperture and the ground, the larger the images will be; but then at the same time the brightness is weakened more and more with the increase of distance.

To construct a Portable Camera Obscura. 1st, Provide a small box or chest of dry wood, about 10 inches broad, and 2 feet long or more, according to the size of the lenses. 2d, In one side of it, as *BD*, fit a sliding tube *EF* with two lenses; or, to have the image at a less distance from the tube, with three lenses, convex on both sides; the diameter of the two outer ones to be about 7 inches, but that of the inner to be less, as $4\frac{1}{2}$ or 5 inches. 3d, At a proper distance, within the box, set up perpendicularly an oiled paper *GH*, so that images thrown upon it may appear on the other side. 4th, In the opposite side, at *A*, make a round hole, for a person to look conveniently through with both eyes. Then if the tube be turned towards the objects, and the lenses be placed by trials at the proper distance, by sliding the tube in and out, the objects will be seen delineated on the paper, erect as before.

The machine may be better accommodated for drawing, by placing a mirror to pass from *e* to *c*; for this will reflect the image upon a rough glass plane, or an oiled paper, placed horizontally at *AB*; and a copy of it may there be sketched with a black-lead pencil.

Another Portable Camera Obscura is thus made. 1st, On the top of a box or chest raise a little turret *HI*, open towards the object *AB*. 2d, Behind the aperture, incline a small mirror *ab* at an angle of 45 degrees, to reflect the rays *aa* and *bb* upon a lens *G* convex on both sides, and included in a tube *GH*. Or the lens may be fixed in the aperture. 3d, At the distance of the focus of this lens place a table, or board *EF*, covered with a white paper, to receive the image *ab*. Lastly, In *MN* make an oblong aperture to look through; and an opening may also be made in the side of the box, for the convenience of drawing.

This sort of camera is easily changed into a show-box, for viewing prints, &c: placing the print at the bottom of the box, with its upper part inwards, where it is enlightened through the front, left open for this purpose, either

by day or candle-light; and the print may be viewed through the aperture in *MN*.—A variety of contrivances for this purpose may be seen described in Harris's Optics, b. ii. sect. 4.—Mr. Storer has also procured a patent for an instrument of this kind, which he calls a delineator; being formed of two double convex lenses and a plane mirror, fitted into a proper box. One lens is placed close to the mirror, making with it an angle of 45 degrees; the other being placed at right angles to the former, and fixed in a moveable tube. If the moveable lens be directed towards the object which is to be viewed or copied, and moved nearer to or farther from the mirror, till the image is distinctly formed on a greyed glass, laid upon that surface of the upper lens which is next the eye, it will be found more sharp and vivid than those formed in the common instruments; because the image is received so near the upper lens. And by increasing the diameter and curvature of the lenses, the effect will be much heightened.

CAMPANI (MATTHEW), an eminent Italian optician, born in the diocese of Spoleto, in the 17th century, but resided chiefly at Rome, where he was very eminent for his mechanical contrivances of optical and philosophical instruments, and for several books on such subjects; particularly relating to pendulums, or timepieces, for the longitude; also to spectacles, and to telescopes, of which it is said he made the very best and largest of his time. It is said it was by his telescopes that the first Cassini made his best observations and chief discoveries in the heavens; and they still show at Paris, among the astronomical antiquities, several of Campani's object-glasses, of 8, 10, and 12 inches diameter. He was curate at Rome, and much re-spected.

CAMPANI (JOSEPH), younger brother and pupil to Matthew, above mentioned, was also very skilful in mechanics and physic, and executed his brother's plans with great ingenuity. They were both living in 1678.

CAMUS (CHARLES-STEVEN-LEWIS), a celebrated French mathematician, examiner of the Royal Schools of Artillery and Engineers, secretary and professor of the Royal Academy of Architecture, honorary member of that of the Marine, and fellow of the Royal Society of London, was born at Cressy en Brie, the 25th of August 1699. His early ingenuity in mechanics and his own entreaties, induced his parents to send him to study at a college in Paris, at 10 years of age; where in the space of two years his progress was so great, that he was able to give lessons in mathematics, and thus to defray his own expenses at the college, without any further charge to his parents. By the assistance of the celebrated Varignon, young Camus soon ran through the course of the higher mathematics, and acquired a name among the learned. He made himself more particularly known to the Academy of Sciences in 1727, by his memoir on the subject of the prize which they had proposed for that year, viz, "To determine the most advantageous way of masting ships;" in consequence of which he was named that year Adjunct-Mechanic to the Academy; and in 1730 he was appointed professor of architecture. In less than three years after, he was honoured with the secretarship of the same; and the 18th of April 1733, he obtained the degree of Associate in the Academy, where he distinguished himself greatly by his memoirs on living forces, or bodies in motion acted on by forces, on the figure of the teeth of wheels and pinions, on pump work, and several other ingenious memoirs.

In 1736 he was sent, in company with Messieurs Clai-

raut, Maupertuis, and Monnier, on the celebrated expedition to measure a degree at the north polar circle; in which he rendered himself highly useful, not only as a mathematician, but also as a mechanician and an artist, branches for which he had a remarkable talent.

In 1741 Camus had the honour to be appointed Pensioner-Geometrician in the Academy; and the same year he invented a gauging-rod and sliding-rule, proper at once to gauge all sorts of casks, and to calculate their contents. About the year 1747 he was named Examiner of the Schools of Artillery and Engineers: and, in 1756, one of the eight mathematicians appointed to examine by a new measurement, the base which had formerly been measured by Picard, between Villejuifive and Juvisi; an operation in which his ingenuity and exactness were of great utility. In 1765 M. Camus was elected a fellow of the Royal Society of London; and died the 4th of May 1768, in the 69th year of his age; being succeeded by the celebrated d'Alembert in his office of Geometrician in the French Academy; and leaving behind him a great number of manuscript treatises on various branches of the mathematics.

The works published by M. Camus are:

1. Course of Mathematics for the use of the Engineers,
4 vols. in 8vo.

2. Elements of Mechanics.

3. Elements of Arithmetic.

And his memoirs in the volumes of the Academy are:

1. Of Accelerated Motions by living forces: vol. for 1728.
2. Solution of a Geomet. Prob. of M. Cramer: 1732.
3. On the figure of the teeth and pinions in clocks: 1733.
4. On the action of a musket-ball, piercing a pretty thick piece of wood, without communicating any considerable velocity to it: 1738.

5. On the best manner of employing buckets for raising water: 1739.

6. A Problem in Statics: 1740.

7. On an Instrument for gauging of vessels: 1741.

8. On the Standard of the Ell Measure: 1746.

9. On the tangents of Points common to several branches of the same curve: 1747.

10. On the operations in measuring the distance between the centres of the pyramids of Villejuifive and Juvisi, to discover the best measure of the degree about Paris: 1754.

11. On the Masting of Ships: Prize tom. 2.

12. The Manner of working Oars: Mach. tom. 2.

13. A Machine for moving many Colters at once: Mach. tom. 2.

CANAL, in general, denotes a long, round, hollow instrument, through which a fluid matter may be conveyed. In which sense, it amounts to the same as what is otherwise called a pipe, tube, channel, &c. Thus the canal of an aqueduct, is the part through which the water passes; which, in the ancient works of this kind, is lined with a coat of mastic of a peculiar composition.

CANAL more particularly denotes a kind of artificial river, often furnished with locks and sluices, and sustained by banks or mounds. They are contrived for divers purposes: some for forming a communication between one place and another; as the canals between Bruges and Ghent, or between Brussels and Antwerp: others for the decoration of a garden, or house of pleasure; as the canals of Versailles, Fontainbleau, St. James's Park, &c: and others are made for draining wet and marshy lands; which last, however, are more properly called water-gangs, drains, ditches, &c.

It is needless to enumerate the many advantages arising from canals and artificial navigations. Their utility is now so apparent, that most nations in Europe give the highest encouragement to undertakings of this kind, wherever they are practicable. Nor did their advantages escape the observation of the ancients; for in the earliest accounts of society we read of attempts to cut through large isthmuses, to make communications by water, either between one sea and another, or between different nations, or distant parts of the same nation, where land-carriage was tedious and expensive.

Egypt is full of canals, dug to receive and distribute the waters of the Nile, at the time of its inundation. They are dry the rest of the year, except the Canal of Joseph, and four or five others, which may be ranked as considerable rivers. There were also subterraneous canals, or tunnels, dug by an ancient king of Egypt, by which those lakes, formed by the inundations of the Nile, were conveyed into the Mediterranean Sea.

A new canal for conveying the waters of the Nile from Ethiopia into the Red Sea without passing into Egypt, was projected by Albuquerque, viceroy of India for the Portuguese, to render Egypt barren and unprofitable to the Turks. And M. Gaildereau attributes the frequency of the plague in Egypt, of late days, to the decay or stopping up of the canals; which happened upon the Turks becoming masters of the country.

Herodotus relates, that the Cnidians, a people of Coria, in Asia Minor, designed to cut through the isthmus which joins that peninsula to the continent; but were superstitious enough to give up the undertaking, because it was interdicted by an oracle.

Several kings of Egypt attempted to join the Red Sea to the Mediterranean; a project which Cleopatra was very fond of. This canal was begun, according to Herodotus, by Necus son of Psammeticus, who desisted from the attempt on an answer from the oracle, after having lost 120 thousand men in the enterprise. It was resumed and completed by Darius son of Hystaspes, or, according to Diidorus and Strabo, by Ptolemy Philadelphus; who relate that Darius relinquished the work on a representation made to him by unskillful engineers, that the Red Sea, being higher than the land of Egypt, would overflow and drown the whole country. It was wide enough for two galleys to pass abreast, and its length was four days sailing. Diidorus adds, that it was also called Ptolemy's river; that this prince built a city at its mouth on the Red Sea, which he called Arsinoë, from the name of his favourite sister; and that the canal might be either opened or shut, as occasion required. Diod. Sic. lib. 1; Strabo, Geog. lib. 17; Herod. lib. 2. Soliman the 2d, emperor of the Turks, employed 50 thousand men in this great work; which was completed under the caliphate of Omar, about the year 635; but it was afterwards allowed to fall into neglect and disrepair; so that it is now difficult to discover any traces of it. Hist. Acad. Scien. ann. 1703, pa. 110.

Both the Greeks and Romans intended to make a canal across the Isthmus of Corinth, which joins the Morea and Achaea, for a navigable passage by the Ionian Sea into the Archipelago. Demetrius, Julius Caesar, Caligula, and Nero, made several unsuccessful efforts to open this passage. But as the ancients were entirely ignorant of the use of water-locks, their whole attention was employed in making level cuts, which is probably the chief reason why they so often failed in their attempts. Charlemagne formed

a design of joining the Rhine and the Danube, to make a communication between the Ocean and the Black Sea, by a canal from the river Almutz which discharges itself into the Danube, to the Reditz, which falls into the Maine, which last falls into the Rhine near Mayence or Mertz: for this purpose he employed a prodigious number of workmen; but he met with so many obstacles from different quarters, that he was obliged to relinquish the attempt.

In China there is scarce a town or village without the advantage either of an arm of the sea, a navigable river, or a canal, by which means navigation is rendered so common, that there are almost as many people on the water as the land. The great canal of China is one of the wonders of art, extending from north to south quite across the empire, from Pekin to Canton, a distance of 825 miles, and was made upwards of 900 years ago. Its breadth and depth are sufficient to carry barks of considerable burthen, which are managed by sails and masts, as well as towed by hand. On this canal it seems the emperor employs near ten thousand ships. It passes through, or by, 41 large cities; there are in it 75 vast locks and sluices, to keep up the water, and pass the ships where the ground will not admit of sufficient depth of channel, besides several thousand draw- and other bridges. Indeed, F. Magalane assures us, there are passages by canals from one end of China to the other, for the length of 600 French leagues: and that a person may go from one end of the empire to the other, either by canals or rivers, except a single day's journey by land in crossing a mountain.

The French at present have many fine canals. That of Briere, otherwise called the Canal of Burgundy, was begun under Henry IV, and finished under the direction of Cardinal Richelieu in the reign of Louis XIII. This canal makes a communication between the Loire and the Seine, and so to Paris. It extends 11 French great leagues from Briere to Montargis, and has 42 locks upon it.

The Canal of Orleans was begun in 1675, for establishing a communication also between the Seine and the Loire. It is considerably shorter than that of Briere, and has only 20 sluices.

The Canal of Bourbon was but lately undertaken: its design is to make a communication from the river Oise to Paris.

But the greatest and most useful work of this kind, is the junction of the Ocean with the Mediterranean by the Canal of Languedoc, called also the Canal of the Two Seas. It was proposed in the reigns of Francis I, and Henry IV, and was begun and finished under Louis XIV; having been planned by Francis Riquet in the year 1666, and finished before his death, which happened in 1680. It begins with a large reservoir 4000 paces in circumference, and 24 feet deep, which receives many springs from the mountain Noire. The canal is about 200 miles in length, extending from Narbonne to Thoulouse, being supplied by a number of rivulets in the way, and furnished with 104 locks or sluices, of about 8 feet rise each. In some places it is carried over bridges and aqueducts of vast height, which give passage underneath to other rivers; and in some places it is cut through solid rocks for a mile together.

The new canal of the lake Ladoga, cut from Volhova to the Neva, by which a communication is made between the Baltic, or rather Ocean, and the Caspian Sea, was begun by the czar Peter the 1st, in 1719: by means of which the English and Dutch merchandise is easily con-

veyed into Persia, without being obliged to double the Cape of Good Hope. There was a former canal of communication between the Ladoga lake and the river Wolga, by which timber and other goods had been brought from Persia to Petersburg; but the navigation of it was so dangerous, that a new one was undertaken.

The Spaniards have several times had in view the digging a canal through the Isthmus of Darien, between North and South America, from Panama to Nombre de Dios, to make a ready communication between the Atlantic and the South Sea, and thus afford a straight passage to China and the East Indies.

In the Dutch, Austrian, and French Netherlands, there is a great number of canals: that from Bruges to Ostend carries vessels of 200 tons. But it would be an endless task to describe the numberless canals in Holland, Germany, Russia, &c. We will therefore only take a view of those in our own country.

In England, that ancient canal from the river Nyne, a little below Peterborough, to the river Witham, three miles below Lincoln, called by the modern inhabitants Caerdeir, may be ranked among the monuments of the Roman grandeur, though it is now most of it filled up. Morton will have it made under the emperor Domitian. Urns and medals have been discovered on the banks of this canal, which appear to confirm that opinion. Yet some authors take it to be a Danish work. It was 40 miles in length; and, so far as appears from the ruins, must have been very broad and deep. Notwithstanding that early beginning, it is but very lately that canals have been revived in this country. They are now however become very numerous, particularly in the counties of York, Lincoln, and Cheshire. Most of the counties between the mouth of the Thames and the Bristol Channel are connected, either by natural or artificial navigations; those upon the Thames and Isis reaching within 20 miles of those upon the Severn.

The canal for supplying London with water by means of the New River, was projected and begun by Mr. Edward Wright, author of the celebrated treatise on Navigation, about the year 1608; but finished by Mr. (afterwards Sir Hugh) Middleton, five years after. This canal commences near Ware, in Hertfordshire, and takes a course of 60 miles before it reaches the cistern at Islington, which supplies several water-pipes that convey it to the city and parts adjacent. In some places it is 30 feet deep, and in others it is conveyed over a valley between two hills, by means of a trough supported by wooden arches, and rising above 23 feet in height.

The Duke of Bridgewater's Canal, projected and executed under the direction of Mr. Brindley, was begun about the year 1759. It was first designed only for conveying coals to Manchester, from a mine in the duke's estate; but has since been applied to many other useful purposes of inland navigation. This canal begins at a place called Worsley Mill, 7 miles from Manchester, where a basin is made capable of holding all the boats, and a great body of water which serves as a reservoir or head to the navigation. The canal runs through a hill by a subterraneous passage, large enough for admitting long flat-bottomed boats, which are towed by a rail on each hand, near three quarters of a mile, to the coal-works. There the passage divides into two channels, one of which goes off 300 yards to the right, and the other as many to the left; and both may be continued at pleasure. The passage is in some

places cut through the solid rock, and in others arched over with brick; and air-funnels, some of which are near 37 yards perpendicular, are cut, at certain distances, through the rock to the top of the hill. The arch at its entrance is about 6 feet wide, and about 5 feet high from the surface of the water; but widens within, so that in some places the boats may pass one another, and at the pits it is 10 feet wide. When the boats are loaded and brought out of the basin, five or six of them are linked together, and drawn along the canal by a single horse, and thus reaching Manchester in a course of 9 miles. It is broad enough for two barges to pass or go abreast; and on one side there is a good road for the passage of the people, and the horses or mules employed in the work. The canal is raised over public roads by means of arches; and it passes over the navigable river Irwell near 50 feet above it; so that large vessels in full sail pass under the canal, while the duke's barges are at the same time passing over them. This canal joins that which passes from the river Mersey towards the Trent, taking in the whole a course of 34 miles.

The Lancaster Canal begins near Kendal, and terminates near Eccleston, comprehending the distance of $72\frac{1}{2}$ miles.

The canal from Liverpool to Leeds is $108\frac{1}{2}$ miles in length: that from Leeds to Selby, $23\frac{1}{2}$ miles; from Chichester to Middlewich, $26\frac{1}{2}$ miles; from the Trent to the Mersey, 88 miles; from the Trent to the Severn, $40\frac{1}{2}$ miles. The Birmingham Canal joins this near Wolverhampton, and is $24\frac{1}{2}$ miles: the Droitwich Canal is $5\frac{1}{2}$ miles: the Coventry Canal, commencing near Lichfield, and joining that of the Trent, is $36\frac{1}{2}$ miles: the Oxford Canal breaks off from this, and is 82 miles: the Chesterfield Canal joins the Trent near Gainsborough, and is 44 miles.

A communication is now formed, by means of this inland navigation, between Kendal and London, by way of Oxford; between Liverpool and Hull, by the way of Leeds; and between the Bristol Channel and the Humber, by the junction formed between the Trent and the Severn. Other schemes have been projected, which the present spirit of improvement will probably soon carry into execution, of opening a communication between the German and Irish seas, so as to reduce a hazardous navigation of more than 800 miles by sea, into a little more than 150 miles by land, or inland navigation; and also of joining the Isis with the Severn; besides many other canals in various parts of England.

In Scotland, a navigable canal between the Forth and Clyde, which divides that country into two parts, was meditated upon more than a century since, for transports and small ships of war. It was again projected in the year 1722, and a survey made; but nothing more was done till 1761, when the then Lord Napier, at his own expense, had a survey, plan, and estimate, made on a small scale. In 1764, the trustees for fisheries, &c, in Scotland, procured another survey, plan, and estimate, of a canal 5 feet deep, which was to cost 79,000 pounds. In 1766, a subscription was obtained by a number of the most respectable merchants in Glasgow, for making a canal 4 feet deep and 24 feet in breadth; but when the bill was nearly obtained in parliament, it was given up on account of the smallness of the scale, and a new subscription set on foot for a canal 7 feet deep, estimated at 150,000 pounds. This obtained the sanction of parliament; and the work was begun in 1768, by Mr. Sineaton the engineer. The extreme length of the canal from the Forth to the Clyde is 35 miles, beginning at the mouth of the Carron, and ending at Dalnuire

Burnfoot on the Clyde, 6 miles below Glasgow, rising and falling 160 feet by means of 39 locks, 20 on the east side of the summit, and 19 on the west, as the tide does not ebb so low in the Clyde as in the Forth by 9 feet; and it was deepened to upwards of 8 feet. This canal was finished a few years since, after having experienced some interruptions and delays, for want of resources, and is esteemed the greatest work of the kind in this island. Vessels drawing 8 feet water, with 19 feet in the beam and 73 feet in length, pass with ease; and the whole enterprise displays the art of man in a high degree. To supply the canal with water was of itself a very great work. There is one reservoir of 50 acres 24 feet deep, and another of 70 acres 22 feet deep, in which many rivers and springs terminate, which it is expected will afford sufficient supply of water at all times.

The Practice of Canal Digging and Inland Navigations.

The particular operations necessary for making artificial navigations depend upon a variety of circumstances. The situation of the ground; the vicinity or connexion of it with rivers; the ease or difficulty with which a proper quantity of water can be obtained: these and many other circumstances necessarily produce great variation in the structure of artificial navigations, and augment or diminish the labour and expense of executing them. When the ground is naturally level, and unconnected with rivers, the execution is easy, and the navigation is not liable to be disturbed by floods: but when the ground rises and falls, and cannot be reduced to a level, artificial methods of raising and lowering vessels must be employed; which also vary according to circumstances.

Sometimes a kind of temporary sluices are employed, to raise boats over falls or shoals in rivers, by a very simple operation. Two pillars of mason-work, with grooves, are fixed, one on each bank of the river, at some distance below the shoal. The boat having passed these pillars, strong planks are let down across the river by pulleys into the grooves; by which means the water is dammed up to a proper height for allowing the boat to pass up the river over the shoal.

The Dutch and Flemings at this day sometimes, when obstructed by cascades, form an inclined plane or rolling-bridge upon dry land, along which their vessels are drawn from the river below the cascade, into the river above it. This, it is said, was the only method employed by the ancients, and is still sometimes used by the Chinese. These rolling-bridges consist of a number of cylindrical rollers which turn easily on pivots. And a mill is commonly built near; so that the same machinery may serve the double purpose of working the mill and drawing up vessels.

But in the present improved state of inland navigation, these falls and shoals are commonly surmounted by means of what are called locks or sluices. A lock is a basin placed lengthwise in a river or canal, lined with walls of masonry on each side, and terminated by two gates placed across the canal, where there is a cascade or natural fall of the country; and so constructed, that the basin being filled with water by an upper sluice to the level of the waters above, a vessel may ascend through the upper gate; or the water in the lock being reduced to the level of the water at the bottom of the cascade, the vessel may descend through the lower gate: for when the waters are brought to a level on either side, the gate on that side may be easily opened.

But as the lower gate is strained in proportion to the

depth of water it supports, when the perpendicular height of the water exceeds 12 or 13 feet, it becomes necessary to have more locks than one. Thus, if the fall be 16 feet, two locks are required, each of 8 feet fall; and if the fall be 25 feet, three locks are necessary, each having 8 feet 4 inches fall.—It is evident that the side-walls of locks should be made very strong: and where the natural foundation is bad, they should be founded on piles and platforms of wood. They should likewise slope outwards, in order to resist the pressure of the earth from behind.

To illustrate this by representations: Plate 6, fig. 1, is a perspective view of part of a canal, with several locks, &c; the vessel *L* being within the lock *AC*.—Fig. 2 is an elevation or upright section along the canal; the vessel *L* about to enter.—Fig. 3, a like section of a lock full of water; the vessel *L* being raised to a level with the water in the superior canal.—And fig. 4 is the plan or ground section of a lock: where *L* is a vessel in the inferior canal; *c*, the under gate; *A*, the upper gate; *GH*, a subterraneous passage for letting water from the superior canal run into the lock; and *KF*, a subterraneous passage for water from the lock to the interior canal.

x and *y* (fig. 1) are the two flood-gates, each of which consists of two leaves, pressing against one another, so as to form an obtuse angle, the better to resist the pressure of the water. The first (*x*) prevents the water of the superior canal from falling into the lock; and the second (*y*) dams up and sustains the water in the lock. These flood-gates ought to be very strong, and to turn freely on their hinges. They should also be made very tight and close, that as little water as possible may be lost. And, to make them open and shut with ease, each leaf is furnished with a long lever *Ab*, *Ab*; *cb*, *cb*.

By the subterraneous passage *GH* (fig. 2, 3, 4) which descends obliquely, by opening the sluice *G*, the water is let down from the superior canal *D*, into the lock, where it is stopped and retained by the gate *c* when shut, till the water in the lock be on a level with the water in the superior canal *D*; as represented in fig. 3. When, on the other hand, the water contained by the lock is to be let out, the passage *GH* must be shut, by letting down the sluice *G*; the gate *A* must also be shut, and the passage *KF* opened by raising the sluice *K*. A free passage being thus given to the water, it descends through *KF*, into the inferior canal, until the water in the lock be on a level with the water in the inferior canal *B*; as represented in fig. 2.

Now suppose it be required to raise the vessel *L* (fig. 2) from the inferior canal *B* to the superior one *D*. If the lock be full of water, the sluice *G* must be shut, as also the gate *A*, and the sluice *K* opened, so that the water in the lock may run out till it becomes level with the water in the inferior canal *B*. When the water in the lock is on a level with the water at *B*, the leaves of the gate *c* are opened by the levers *cb*, which is easily performed, the water on each side of the gate being in equilibrio; the vessel then sails into the lock. After this, the gate *c* and the sluice *K* are shut, and the sluice *G* opened, in order to fill the lock, till the water in the lock, and consequently the vessel, be upon a level with the water in the superior canal *D*; as is, represented in fig. 3. The gate *A* is then opened, and the vessel passes into the canal *D*.

Again, let it be required to make a vessel descend from the canal *D* into the inferior canal *B*. If the lock be empty as in fig. 2, the gate *c* and sluice *K* must be shut, and the upper sluice *G* opened, so that the water in the

lock may rise to a level with the water in the upper canal *D*. Then, opening the gate *A*, the vessel will pass through into the lock. This done, shut the gate *A* and the sluice *G*; then open the sluice *K*, till the water in the lock be on a level with the water in the inferior canal; this done, the gate *c* is opened, and the vessel proceeds into the canal *B*, as was required.

Other contrivances have lately been made for raising and lowering the vessels between the under and upper canal.

CANCER, the *Crab*, one of the twelve signs of the zodiac, usually drawn on the globe in the form of a crab, and in books of astronomy denoted by a character resembling the number sixty-nine, turned sideways, thus ϖ .

The number of stars in the sign Cancer, Ptolemy makes 13, Tycho 15, Bayer and Hevelius 29, and Flamsteed 83.

Tropic of CANCER, a little circle of the sphere parallel to the equinoctial, and passing through the beginning of the sign Cancer.

CANDLEMAS, or the *Purification*, a feast of the church, held on the 2d of February, in memory of the purification of the Virgin; taking its name of Candlemas, either from the number of lighted candles used by the Romish church in the processions of this day, or because that the church then consecrated candles for the whole year.

CANES *Venatici*, the *Hounds*, or the *Greyhounds*, one of the new constellations of the northern hemisphere, which Hevelius has formed out of the unformed stars of the old catalogues. These two dogs are further distinguished by the names of Asterion and Chara. They contain 23 stars according to Hevelius, but 25 in the British catalogue.

CANICULAR, a name given by many of the earlier astronomers to the constellation which we call the Lesser Dog, and Canis Minor, but some Procyon and Antecanis. See CANIS MINOR.

It is also used for one of the stars of the constellation Canis Major; called also simply the Dog-star; and by the Greeks Σειριος, Sirius. It is situated in the mouth of the constellation, and is the largest and brightest of all the stars in the heavens. From the heliacal rising of this star, that is, its emersion from the sun's rays, which now happens with us about the 11th of August, the ancients reckoned their Dies Caniculares, or Dog-days.

The Egyptians and Ethiopians began their year at the heliacal rising of Canicular; reckoning to its rise again the next year, which is called the *Annus Canarius*.

CANICULAR Days, or Dog-days, denote a certain number of days, before and after the heliacal rising of canicular, or the dog-star, in the morning. The ancients imagined that this rising of the star occasioned the sultry weather usually felt in the latter part of the summer, or dog-days; with all the distempers of that sickly season: Homer's Il. lib. 5, v. 10, and Virgil's En. lib. 10, v. 270. Some authors say, from Hippocrates and Pliny, that the day this star first rises in the morning, the sea boils, wine turns sour, dogs begin to grow mad, the bile increases and irritates, and all animals grow languid; also that the diseases it usually occasions in men, are burning fevers, dysenteries, and phrenesies. The Romans sacrificed a brown dog every year to Canicular at his rising, to appease its rage. All this however arose from the groundless idea that the dog-star, so rising, was the occasion of the extreme heat and the diseases of that season: for the rising of the star not only varies, in any one year, as the latitude varies, but is always later and later every year in all latitudes; so that in time the star may, by the same

rule, be charged with bringing frost and snow, when he rises in winter.

The dog-days were commonly reckoned about 40, viz, 20 days before and 20 days after the heliacal rising; and almanac-makers have usually set down the dog-days in their almanacs to the changing time of the star's rising, by which means they had at length fallen considerably after the hottest time of the year, till of late we have observed an alteration of them in the almanacs, and very properly, from July 3 to August 11. For, by the dog-days, the ancients meant to express the hottest time of the year, which is commonly during the month of July, about which time the dog-star rose heliacally in the time of the most ancient astronomers that we know of: but the precession of the equinoxes has carried this heliacal rising into a much later and cooler part of the year; and because Hesiod tells us that the hot time of the year ends on the 50th day after the summer solstice, which brings us to about August 10 or 11, the above alteration appears to be very proper.

CANICULAR Year, denotes the Egyptian natural year, which was computed from one heliacal rising of Canicula to the next. This year was also called annus canarius, and annus cypicus; and by the Egyptians themselves the Sethic year, from Seth, by which name they called Sirius. Some call it also the heliacal year. This year consisted ordinarily of 365 days, and every 4th year of 366; by which means it was accommodated to the civil year, like the Julian account. And the reason why they chose this star, in preference to others, to compute their time by, was not only the superior brightness of that star, but because in Egypt its heliacal rising was a time of very singular note, as coinciding with the greatest augmentation of the Nile, the reputed father of Egypt. Ephestion adds, that from the aspect of canicula, its colour, &c, the Egyptians drew prognostics concerning the rise of the Nile; and according to Florus, predicted the future state of the year. So it is no wonder that the first rising of this star was observed with great attention. Bainbrigge, *Canicula*, cap. 4, p. 26.

CANIS Major, the *Great Dog*, a constellation of the southern hemisphere, below the feet of Orion, and one of the old 48 constellations. The Greeks, as usual, have many fables of their own about the exaltation of the dog into the skies; but the origin of this constellation, as well as its other name Sirius, lies more probably among the Egyptians, who carefully watched the rising of this star, and by it judged of the swelling of the Nile, calling the star the sentinel and watch of the year; and hence, according to their manner of hieroglyphic writing, represented it under the figure of a dog. They also called the Nile Sirius; and hence their Osiris.

The stars in this constellation, Ptolemy makes 29; Tycho however observed only 13, and Hevelius 21; but in Flamsteed's catalogue they are 31.

CANIS Minor, a constellation of the northern hemisphere, just below Gemini, and is one of the 48 old constellations. The Greeks fabled that this is one of Orion's hounds; but the Egyptians were most probably the inventors of this constellation, and they may have given it this figure to express a little dog, or watchful creature, going before, as conductor of the larger, or rising before it: and hence the Latins have called it Antecanis, the star before the dog.

The stars in this constellation are, in Ptolemy's cata-

logue 2, the principal of which is the star Procyon; in Tycho's, 5; in Hevelius's, 13; and in Flamsteed's, 14.

CANNON, in Military Affairs, a long round hollow engine, made of iron or brass, &c, for throwing balls, &c, by means of gunpowder. The length is distinguished into three parts; the first reinforce, the second reinforce, and the chase: the inside hollow where the charge is lodged, being also called the chase, or bore. But for the several parts and members of a cannon, see **ASTRAGAL**, **BASERING**, **BORE**, **BRECH**, **CASCABEL**, **CHASE**, **MUZZLE**, **OGE**, **REINFORCE-RING**, **TRUNNIONS**, &c. See also **GUN** and **GUNNERY**.

Cannon were first made of several bars of iron adapted to each other lengthways, and hooped together with strong iron rings. They were employed in throwing stones and metal of several hundred weight. Others were made of thin sheets of iron rolled up, and hooped: and on emergencies they have been made of leather, with plates of iron or copper. They are now constituted of cast-iron or brass; being cast solid, and the tube bored out of the middle by means of a very strong machine for that purpose. When or by whom cannon were first invented is uncertain.

Larrey makes brass cannon the invention of J. Owen; and asserts that the first known in England, were in 1535; and further that iron cannon were first cast here in 1547. He acknowledged that cannon were known before; and remarks that at the battle of Cressy, in 1346, there were 5 pieces of cannon in the English army, which were the first ever seen in France. Mezeray also observes, that King Edward struck terror into the French army, by 5 or 6 pieces of cannon; it being the first time they had met such thundering machines.

In the list of aids raised for the redemption of King John of France, in 1368, mention is made of an officer in the French army called Master of the King's Cannon, and of his providing 4 large cannon for the garrison of Harfleur. But Father Daniel, in his Life of Philip of Valois, produces a proof from the records of the chamber of accounts at Paris, that cannon and gunpowder were used in the year 1338. And Du-Cange even finds mention of the same engines in Froissart, and other French historians, some time earlier.

The Germans carry the invention of cannon farther back, and ascribe it to Albertus Magnus, a Dominican monk, about the year 1250. But Isaac Vossius finds cannon in China upwards of 1700 years ago; being used by the emperor Kitey, in the year of Christ 85. The ancients too, of Europe and Asia, had their fiery tubes, or Cannæ, which being loaded with pitch, stones, and iron-balls, were exploded with a vehement noise, smoke, and great effect.

Cannon were formerly made of a very great length, which rendered them exceedingly heavy, and their use very troublesome and confined. But it has lately been found by experiment, that there is very little added to the force of the ball by a great length of the cannon; and therefore they have very properly been much reduced both in their length and weight, and rendered easily manageable on all occasions. They were formerly distinguished by many hard and terrible names, but are now only named from the weight of their ball; as a 6 pounder, a 12 pounder, a 24 pounder, or a 36 pounder, which is the largest size now used by the English for battering.

CANON, in Algebra, Arithmetic, Geometry, &c, is a general rule for resolving all cases of a like nature with the:

present inquiry. Thus the last step of every equation is a canon, and if turned into words, becomes a rule to resolve all cases or questions of the same kind with that proposed:

Tables of sines, tangents, &c, whether natural or artificial, are also called canons.

CANON, in Ancient Music, is a method of determining the intervals of musical notes. Ptolemy, rejecting the Aristoxenian way of measuring the intervals in music by the magnitude of a tone, formed by the difference between a diapente and a diatessaron, thought that they should be distinguished by the ratios which the sounds terminating those intervals bear to one another, when considered according to their degree of acuteness or gravity; which, before Aristoxenus, was the old Pythagorean method. He therefore made the diapason consist in a double ratio; the diapente consist in a sesquialterate; the diatessaron, in a sesquiterian; and the tone itself, in a sesquioctave; and all the other intervals, according to the proportion of the sounds that terminate them: therefore, taking the canon, for a determinate line of any length, he shows in what manner it must be cut, to represent the respective intervals: and this method answers exactly to experiments in the different lengths of musical chords. From this canon, Ptolemy and his followers have been called Canonici; as those of Aristoxenus were called Musici.

CANON, in Modern Music, is a short composition of two or more parts, in which one leads and the other follows; and is a fugue so bound up, or restrained, that the following part or parts must precisely repeat the same notes, with the same degrees rising or falling, which were expressed by the leading part; it is therefore tied to so strict a rule, that it is called canon.

Pascal CANON, a table of the moveable feasts, showing the day of Easter, and the other feasts depending on it, for a cycle or period of 19 years. It is said that the Pascal Canon was the calculation of Eusebius of Cesarea, and that it was made by order of the council of Nice.

CANOPUS, a name given by some of the old astronomers to a star under the 2d bend of Eridanus. These writers say that the river in the heavens is not the Eridanus, but the Nile, and that this star commemorates an island made by that river, which was called by the same name.

CANOPUS is also the name of a bright star of the first magnitude in the rudder of Argo, one of the southern constellations. Its situation, as given by several authors, at different times, is as follows:

Authors	Dates	Longit.	Lat.	Rt. Ascen.	Declin. So.
F. Thomas	Jan. 1682	8° 25'	52°	75° 15'	93° 32' 20"
F. Noel	1697			93° 54'	52° 29'
Dr. Halley	1700	10	52° 72'	49	
F. Feuille	Mar. 1709				52° 30' 4"

CANTALIVERS, in Architecture, are the same with modillions, except that the former are plain, and the latter carved. They are both a kind of cartouches, set at equal distances under the corona of the cornice of a building.

CANTON (John), an ingenious natural philosopher, was born at Stroud, in Gloucestershire, in 1718; and was placed, when young, under the care of Mr. Davis, an able mathematician of that place, with whom he learnt the rudiments of arithmetic, &c. He next proceeded to higher parts of the mathematics, and particularly to algebra and astronomy, in which he had made a considerable progress, when his father took him from school and set him to learn his own business, which was that of a broad-cloth weaver.

This circumstance did not check his zeal for acquiring knowledge. All his leisure time was devoted to the assiduous cultivation of science; and he had now acquired a sufficient knowledge of astronomy to calculate lunar eclipses and other phenomena, and to construct various kinds of sun-dials, which he did at times when he ought to have slept, and without the knowledge of his father; who feared that the prosecution of such studies might injure his health. It was during this discouragement, and at these hours, that he computed, and cut upon stone, with no better an instrument than a common knife, the lines of a large upright sun-dial, on which, beside the hour of the day, were shown the sun's rising, his place in the ecliptic, and some other particulars. When this was finished and made known to his father, he permitted it to be placed against the front of his house, where it excited the admiration of several neighbouring gentlemen, and introduced young Canton to their acquaintance, which was followed by the offer of the use of their libraries. In the library of one of these gentlemen he found Martin's Philosophical Grammar, which was the first book that gave him a taste for natural philosophy. In the possession of another gentleman he first saw a pair of globes; a circumstance that afforded him great pleasure, from the great ease with which he could resolve those problems he had hitherto been accustomed to compute.

Among other persons with whom our author became acquainted in early life, was Dr. Henry Miles of Tooting; who perceiving that he possessed abilities too promising to be confined within the narrow limits of a country town, prevailed on his father to permit him to come to London. Accordingly he arrived at the metropolis the 4th of March 1737, and resided with Dr. Miles at Tooting till the 6th of May following; when he articled himself, for the term of 5 years, as an assistant to Mr. Samuel Watkins, master of an academy in Spital Square. In this situation his ingenuity, diligence, and prudence, were so distinguished, that on the expiration of his servitude in May 1742, he was taken into partnership with Mr. Watkins for 3 years; which gentleman he afterwards succeeded in the school, and there continued during his whole life.

Towards the end of 1745, electricity received a great improvement by the discovery of the famous Leyden phial. This event turned the thoughts of most of the philosophers of Europe to that branch of natural philosophy; and Canton, who was one of the first to repeat and to pursue the experiment, found his endeavours rewarded by many discoveries.—Towards the end of 1749, he was engaged with his friend, the late ingenious Benjamin Robins, in making experiments to determine the height to which rockets may be made to ascend, and at what distance their light may be seen.—In 1750 was read at the Royal Society Mr. Canton's "Method of making Artificial Magnets, without the use of, and yet far superior to, any natural ones." This paper procured him the honour of being elected a member of the Society, and the present of their gold medal. The same year he was complimented with the degree of M. A. by the university of Aberdeen. And in 1751 he was chosen one of the council of the Royal Society.

In 1752, our philosopher was so fortunate as to be the first person in England who, by attracting the electric fire from the clouds during a thunder-storm, verified Dr. Franklin's hypothesis of the similarity of lightning and electricity. Next year his paper entitled "Electrical Ex-

periments, with an attempt to account for their several phenomena," was read at the Royal Society; in which Mr. Canton mentions his having discovered, by many experiments, that some clouds were in a positive, and some in a negative state of electricity: a discovery which was also made by Dr. Franklin in America much about the same time. This circumstance, together with our author's constant defence of the doctor's hypothesis, induced that excellent philosopher, on his arrival in England, to pay Mr. Canton a visit, and gave rise to a friendship which ever after continued between them.—In the *Laües' Diary* for 1756, our author answered the prize query that had been proposed in the preceding year, concerning the meteor called shooting-stars. The solution, though only signed A. M. was so satisfactory to his friend, the excellent mathematician Mr. Thomas Simpson, who then conducted that ingenious and useful little work, that he sent Mr. Canton the prize, accompanied with a note, in which he said he was sure that he was not mistaken in the author of it, as no correspondent besides him, could have given that answer.—Our philosopher's next communication to the public was a letter in the Gentleman's Magazine for September 1759, on the electrical properties of the tourmalin, in which the laws of that wonderful stone are laid down in a very concise and elegant manner. On the 13th of December in the same year, was read at the Royal Society, An attempt to account for the Regular Diurnal Variation of the Horizontal Magnetic Needle; and also for its Irregular Variation at the time of an Aurora Borealis. A complete year's observations of the diurnal variations of the needle are annexed to the paper.—Nov. 5, 1761, our author communicated to the Royal Society an account of the Transit of Venus of the 6th of June that year, observed in Spital-square; and in 1762 a letter addressed by him to Dr. Franklin was read, containing some remarks on Mr. Delaval's electrical experiments. On the 16th of Dec. the same year, another curious addition was made by him to philosophical knowledge, in a paper entitled Experiments to prove that Water is not Incompressible. And on Nov. 8, the year following, were read before the Society, his farther Experiments and Observations on the Compressibility of Water, and some other Fluids. These experiments are a complete refutation of the famous Florentine experiment, which so many philosophers have mentioned as a proof of the incompressibility of water. For this communication he received the Society's gold medal.

In 1768 our author communicated to the Society, An easy method of making a phosphorus that will imbibe and emit light like the Bolognian Stone; with experiments and observations. When he first showed to Dr. Franklin the instantaneous light acquired by some of this phosphorus from the near discharge of an electrified bottle, the doctor immediately exclaimed, "And God said, Let there be light, and there was light."

The Dean and Chapter of St. Paul's having, in a letter, dated March 6, 1769, requested the opinion of the Royal Society relative to the best method of fixing electrical conductors to preserve that cathedral from injury by lightning, Mr. Canton was one of the committee appointed to take the letter into consideration, and to report their opinion thereon. The gentlemen who joined him in this business were, Mr. Delaval, Dr. Franklin, Dr. Watson, and Mr. Wilson. Their report was made on the 8th of June following; and the mode recommended by them has been

VOL. I.

carried into execution. Our author's last communication to the Royal Society was a paper read Dec. 21, 1769, containing Experiments to prove that the Luminousness of the Sea arises from the Putrefaction of its animal Substances.

Besides the papers above mentioned, Mr. Canton wrote a number of others, both in the earlier and the latter parts of his life, which appeared in several publications, and particularly in the Gentleman's Magazine.—He died of a dropsy, the 22d of March, 1772, in the 54th year of his age.

CAPACITY, is the solid content of any body. Also our hollow measures for corn, beer, wine, &c, are called measures of capacity.

CAPACITY, in the Modern Doctrine of Heat, signifies the proportional capability of a given quantity of any substance to absorb and retain caloric; or that disposition or property by which various bodies respectively require more or less of this fluid to superinduce any given temperature in a given mass. See CALORIC and TEMPERATURE.

CAPE, or Promontory, is any high land running out with a point into the sea; as Cape Verde, Cape Horn, the Cape of Good Hope, &c.

CAPELLA, a bright star of the first magnitude, in the left shoulder of Auriga.

CAPILLARY Tubes, in Physics, are very minute pipes, whose canals are exceedingly narrow; being so called from their resemblance to a hair in smallness. Their usual diameter may be from $\frac{1}{20}$ to $\frac{1}{50}$ of an inch: though Dr. Hooke assures us that he drew tubes in the flame of a lamp much smaller, and resembling a spider's thread.

The Ascent of Water, &c, in capillary tubes, is a noted phenomenon in philosophy. Take several small glass tubes, of different diameters, and open at both ends; immerse them a little way in water, and the fluid will be seen to stand higher in the tubes than the surface of the water without, and higher as the tube is smaller, almost in the reciprocal ratio of the diameter of the tube; and that both in open air and in vacuo. The greatest height to which Dr. Hooke ever observed the water to stand, in the smallest tubes, was 21 inches above the surface in the vessel.

From this property, of a higher ascent in smaller tubes, a neat experiment exhibits a pleasing appearance in this manner: Select a number of these glass tubes all different in their diameter, from the very smallest to the largest size; fix these against a small piece of board, all parallel and near to each other, with their lower ends all on a level, and so as that the tubes may succeed each other in a regular gradation, from the smallest to the largest; then dip the whole machine into water with the lower ends equally immersed, and it will be seen that, by the fluid ascending to different heights in the tubes, the tops of the columns will appear to form a regular curve line, being highest in the smallest tube, and lowest in the largest; and if the water be a little tinged with cochineal, or ink, &c, it will render the effect more visible and pleasing.—A more pleasing variety of this experiment is made in the following manner: Take two equal square pieces of perfectly flat glass, of any convenient size, 6 or 8 inches, for instance, on each side; connect two of their equal edges close together by any means, but separate their opposite edges a little from each other, by fixing a small bit of chip, &c, between them, so as to give the two the appearance of a very thin wedge, which will represent, and have the effect of,

2 N

an infinite number of contiguous tubes as disposed parallel to the said closed and opened edges; for then, on dipping the bottoms in the coloured water, this will be seen to ascend up between the two planes, highest on the side next their closed edges, but gradually lower towards the opposite sides, the top of the fluid forming a regular hyperbolic curve line, to which the closed edges and the bottom are seen as the asymptotes.

This ascent and suspension of the water in the tube, is by Dr. Jurin, Mr. Hauksbee, and other philosophers, ascribed to the attraction of the periphery of the concave surface of the tube, to which the upper surface of the water is contiguous and adheres.

This does not however happen uniformly the same in all fluids, some standing higher than others; and in quicksilver the contrary takes place, as that fluid stands lower within the tube than its surface in the vessel, and the lower as the tube is smaller. See Philos. Trans. No. 355, &c., or Cote's Hydr. and Pneum. Lect. p. 265. But these effects suppose that the tubes are used in the clean state in which they are naturally presented; for, by certain precautions, mercury may be shown to have a like elevation above the level. And if the interior of these tubes be coated over with greasy matter, such as oil or tallow, the usual effect will not take place, as the fluid will retain its level.

Another phenomenon of these tubes is, that such of them as would only naturally discharge water by drops, when electrified, yield a continued and accelerated stream; and the acceleration is proportional to the smallness of the tube: indeed, the effect of electricity is so considerable, that it produces a continued stream from a very small tube, out of which the water had not before been able to drop. Priestley's Hist. Electr. 8vo, vol. 1, p. 171, ed. 3d.

The celebrated philosopher, Laplace, has written pretty fully on the theory of this capillary attraction, confirming the opinion of Jurin and Hauksbee, &c., above mentioned, and explaining it by mathematical calculations, in the Supplement to the 10th book of his Celestial Mechanics, on Capillary Attraction. On this subject, see also Dr. Young's paper on the cohesion of fluids, in the Philos. Trans. for 1805, or in his Natural Philos. vol. 2; or Gregory's Mechanics, vol. 1, p. 393; or, translation of Huüy's Nat. Philos. vol. 1, p. 158; Nicholson's Journal, Nos. 74, 76, N.S.; or Retrospect of Philosophical Discoveries, No. 10.

Among the various methods of determining the diameter of a uniform capillary tube, the following appears the best and most accurate. Pour into the tube a certain quantity of mercury, whose weight in troy grains is w , and measure carefully the length, l , of the tube which it occupies, then is the diameter, $d = 0.192523 \sqrt{\frac{w}{l}}$. For the specific gravity of mercury being 13568, a cubic inch weighs 3435·16 grains: hence, 1 : $d^2 l \times 785398 :: 3435\cdot16$ grains : w : Whence, multiplying extremes and means, &c., we get $d = \sqrt{\frac{w}{3435\cdot16 \times 785398 \times l}} = 0.192523 \sqrt{\frac{w}{l}}$.

CAPITAL, in Architecture, the uppermost part of a column or pilaster, serving as a head or crowning to it, being placed immediately over the shaft, and under the entablature. It is made differently in the different orders, and is that indeed which chiefly distinguishes the orders themselves.

CAPITAL of a Bastion, is an imaginary line dividing any work into two equal and similar parts; or a line drawn from the angle of the polygon to the point of the bastion, or from the point of the bastion to the middle of the gorge.

CAPONIERE, or CAPONNIERE, in Fortification, is a passage made from one work to another, of 10 or 12 feet wide, and about five feet deep, covered on each side by a parapet, terminating in a glacis or slope: sometimes it is covered with planks and earth.

CAPRA, or the *She-goat*, a name given to the star Capella, on the left shoulder of Auriga; and sometimes to the constellation Capricorn. Some again represent Capra as a constellation in the northern hemisphere, consisting of 3 stars, comprised between the 45th and 55th degree of latitude. The poets fable her to be Anathea's goat, which suckled Jupiter in his infancy.

CAPRICORN, the *Goat*, a southern constellation, and the 10th sign of the zodiac, as also one of the 48 original constellations received by the Greeks from the Egyptians. The figure of this sign is drawn as having the fore part of a goat; but the hinder part of a fish; and sometimes simply under the form of a goat. In writing, it is denoted by a character representing the crooked horns of a goat's head, thus φ .

The stars in this constellation, in Ptolemy's and Tycho's catalogue, are 28; in that of Hevelius, 29; though it is to be remarked that one of those in the tail, of the 6th magnitude, marked the 27th in Tycho's book, was lost in Hevelius's time. Flamsteed gives 51 stars to this sign.

Tropic of CAPRICORN, a small circle of the sphere, parallel to the equator, passing through the beginning of Capricorn, or the winter solstice, or the point of the sun's greatest south declination.

CAPSTAN, a large massy column shaped like a truncated cone; being set upright on the deck of a ship, and turned by levers or bars, passing through holes in its upper extremity. The capstan is a kind of perpetual lever, or an axis-in-peritrochion, which, by means of a strong rope or cable passed round serves to raise very great weights; such as to hoist sails, to weigh the anchors, to draw the vessels on shore, and hoist them up to be refitted, &c.

CAPUT DRACONIS, or dragon's head, a name given by some to a fixed star of the first magnitude, in the head of the constellation Draco.

CARACT, or CARAT, a name given to the weight which expresses the degree of goodness or fineness of gold. The whole quantity of metal is considered as consisting of 24 parts, which are the carats; so that the carat is the 24th part of the whole: this carat is divided into 4 equal parts, called grains of a carat, and the grains into halves and quarters.

When gold is purified to the utmost degree possible, so that it loses no more by further trials, it is considered as quite pure, and said to be 24 carats fine; if it lose 1 carat, or 1-24th in purifying, it was of 23 carats fine; and if it lose 2 carats, it was 22 carats fine; and so on.

CARCASS, is a hollow case formed of ribs of iron, and covered over with pitched cloth, &c., about the size of bomb-shells; or sometimes made all of iron except two or three holes for the fire to blaze through. These were filled with various combustibles, to fire houses, when thrown out of mortars into besieged places.

CARCAVI (PETER DE), was born at Lyons, but in what

year is not known. He was counsellor to the Parliament of Toulouse, afterwards counsellor to the grand council, and keeper of the king's library. He was appointed geometerician to the French Academy of Sciences in 1666, and died at Paris in 1684. There are extant some letters of his, printed among those of Des Cartes.

CARDAN (HIERONYMUS, OR JEROM), one of the most extraordinary geniuses of his age, was born at Pavia, in Italy, Sept. 24, 1501. At 4 years old he was carried to Milan, his father being an advocate and physician in that city: at the age of 20 he entered the university of the same city, and prosecuted his studies with great success. In 1524 he went to Padua, and the same year was admitted to the degree of master of arts, and the year following, that of doctor of physic. He married about the year 1531; and became professor of mathematics at Milan in 1533. In 1559 he was admitted a member of the college of physicians at Milan; in 1543 he read public lectures in medicine there, and the same at Pavia the year following; but in consequence of non-payment of his salary, he discontinued them, and returned to Milan.

In 1552 he went into Scotland, having been sent for by the archbishop of St. Andrew's, to cure him of an afflicting asthma, after trying the physicians of the king of France and of the emperor of Germany, without receiving any benefit. He began to recover from the day that Cardan prescribed for him; our author returned at the end of 6 weeks and 3 days, leaving him prescriptions which in two years wrought a complete cure. On this visit Cardan passed through London, and calculated King Edward's nativity; being famous for his pretensions in astrology, as well as his skill in mathematics and medicine. Returning to Milan, after 4 months absence, he remained there till the beginning of Oct. 1552; and then went to Pavia, from whence he was invited to Bologna in 1562. He taught in this last city till the year 1570; at which time he was thrown into prison; but some months after he was sent home to his own house. He quitted Bologna in 1571; and went to Rome, where he lived for some time without any public employment. He was however admitted a member of the college of physicians, and received a pension from the Pope, till the time of his death, which happened at Rome on the 21st of September 1575.

Cardan, at the same time that he was one of the greatest geniuses and most learned men of his age, in all the sciences, was one of the most eccentric and fickle in conduct of all men that ever lived; despising every good principle and opinion, and without one friend in the world. The same capriciousness that was remarkable in his outward conduct, is also observable in the composition of his numerous and elaborate works. In many of his treatises the reader is stopped almost every moment by the obscurity of his text, or by digressions from the point in hand. In his arithmetical writings there are several discourses on the motions of the planets, on the creation, on the Tower of Babel, and such like. And the apology which he made for these frequent digressions is, that he might by that means enlarge and fill up his book, his bargain with the bookseller being at so much per sheet; and that he worked as much for his daily support as for fame. The Lyons edition of his works, printed in 1663, consists of no less than 10 volumes folio.

In fact, when we consider the transcendent qualities of Cardan's mind, it cannot be denied that he cultivated it with every species of knowledge, and made a greater progress in philosophy, in the medical art, in astronomy, in

mathematics, and the other sciences, than the most part of his contemporaries who had applied themselves but to one of those sciences. In particular, he was perhaps the best algebraist of his time, a science in which he made great improvements; and his labours in cubic equations especially have rendered his name immortal, the rules for solving them having ever since borne his name, and are likely to do so as long as this science exists, although he received the first knowledge of them from another person; the account of which, and his disputes with Tartalea, have been given at large under the article ALGEBRA.

Scaliger affirms, that Cardan, having by astrology predicted and fixed the time of his death, abstained from all food, in order that his prediction might be verified, and that his continuance to live might not discredit his art. It is further remarkable, that Cardan's father also died in this manner, in the year 1524, having abstained from sustenance for nine days. Our author, too, informs us that his father had white eyes, and could see in the night-time.

CARDINAL Points, in Geography, are the east, west, north, and south points of the horizon.

CARDINAL Points of the Heavens, or of a Nativity, are the rising and setting of the sun, the zenith and nadir.

CARDINAL Signs, are those at the four quarters, or the equinoxes and solstices, viz, the signs Aries, Libra, Cancer, and Capricorn.

CARDINAL Winds, are those that blow from the four cardinal points, viz., the east, west, north, and south winds.

CARDIOIDE, the name of a curve so called by Casilliani.—But it was first treated of by Koersma, and by Carré. See Philos. Trans. 1741, and Mémoires de l'Acad. 1705.

The *Cardioide* is thus generated. APB is a circle, and AB its diameter. Through one extremity A of the diameter draw any number of lines APQ , cutting the circle in P ; upon these set off always PQ equal to the diameter AB ; so shall the points Q always lie in the curve of the cardioide.

From this generation of the curve, its chief properties are evident, viz. that-

everywhere $PQ = AB$,
 CQ , or QQ is $= AC$ or $2AB$,
 $AQ = AB \pm AP$,
 P always bisects QQ .

The cardioid is an algebraical curve, and the equation expressing its nature is this: putting

$$\begin{aligned} a &= AB \text{ the diameter,} \\ x &= ad \text{ perp. to } ae, \\ y &= dq \text{ perp. to } ad; \text{ then is} \\ -6ay^3 + 2x^2y^2 - 6ax^2y + x^4 \\ + 12a^2y^2 - 8ax^2y + 3a^2x^2 \end{aligned} \quad \left. \right\} = 0,$$

which is the equation of the curve.

Many properties of the cardiode may be seen in the places above cited.

CARRE' (LEWIS), an ingenious mathematician and philosopher, was born in the year 1663, in the province of Brie in France. His father, a substantial farmer, intended him for the church. But, after going through the usual course of education for that purpose, and having an utter aversion to it, he refused to enter upon that function; by

which he incurred his father's displeasure. His resources being thus cut off, he was obliged to quit the university, and look into the world for some employment. In this exigency he had the good-fortune to be engaged as an amanuensis by the celebrated Father Malebranche; by which he found himself at once transported from the mazes of scholastic darkness, to the source of the most brilliant and enlightened philosophy. Under this great master he studied mathematics and the most sublime metaphysics. After seven years spent in this excellent school, M. Carré found it necessary, in order to procure himself some less precarious establishment, to teach mathematics and philosophy in Paris; but especially that philosophy which, on account of its tendency to improve our morals, he valued more than all the mathematics in the world. And accordingly his greatest care was to make geometry serve as an introduction to his well-beloved metaphysics.

Most of Carré's pupils were of the fair sex. The first of these, who soon perceived that his language was rather the reverse of elegant and correct, told him pleasantly that, as an acknowledgment for the pains he took to teach her philosophy, she would teach him French; and he ever after owned that her lessons were of great service to him. In general he seemed to set more value on the genius of women than that of men.

M. Carré, although he gave the preference to the metaphysics, did not neglect mathematics; and while he taught both, he took care to make himself acquainted with all the new discoveries in the latter. This was all that his constant attendance on his pupils would allow him to do, till the year 1697, when M. Varignon, so remarkable for his extreme scrupulousness in the choice of his élèves, took M. Carré to him in that station. Soon after, viz, in the year 1700, our author, thinking himself bound to do something that might render him worthy of that title, published the first complete work on the Integral Calculus, under the title of "A method of measuring Surfaces and Solids, and finding their Centres of Gravity, Percussion, and Oscillation." He afterwards discovered some errors in the work, and was candid enough to own and correct them in a subsequent edition.

In a short time M. Carré became associate, and at length one of the pensioners of the Academy. And as this was a sufficient establishment for one, who knew so well how to keep his desires within just bounds, he gave himself up entirely to study; and as he enjoyed the appointment of Mechanician, he applied himself more particularly to mechanics. He took also a survey of every branch relating to music; such as the doctrine of sounds, the description of musical instruments; though he despised the practice of music, as mere sensual pleasure. Some sketches of his ingenuity and industry in this way may be seen in the Memoirs of the French Academy of Sciences. He also composed some treatises on other branches of natural philosophy, and some on mathematical subjects; all which he bequeathed to that illustrious body; though it does not appear that any of them have yet been published. It is not unlikely that he was hindered from putting the last hand to them by a train of disorders proceeding from a bad digestion, which, after harassing him during the course of five or six years, at length brought him to the grave in 1711, at 48 years of age.

His memoirs printed in the volumes of the Academy, with the years of the volumes, are as below.

1. Rectification of Curve Lines by Tangents : 1701.
2. Solution of a Prob. proposed to Geometriicians, &c. 1701.
3. Reflections on the Table of Equations : 1701.
4. On the Cause of the Refraction of Light : 1702.
5. Why the Tides are always augmenting from Brest to St. Malo, and diminishing along the coasts of Normandy : 1702.
6. Number and Names of Musical Instruments : 1702.
7. On the Vinegar which causes small stones to roll upon an inclined plane : 1703.
8. On the Rectification &c, of the Caustics by reflection : 1703.
9. Method for the Rectification of Curves : 1704.
10. Observations on the Production of Sound : 1704.
11. On a Curve formed from a Circle : 1705.
12. On the Refraction of Musket-balls in water, and on the Resistance of that fluid : 1705.
13. Experiments on Capillary Tubes : 1705.
14. On the Proportion of Pipes to have a determinate quantity of water : 1705.
15. On the Laws of Motion : 1706.
16. On the Properties of Pendulums ; with some new properties of the Parabola : 1707.
17. On the Proportion of Cylinders that their sounds may form the musical chords : 1709.
18. On the Elasticity of the Air : 1710.
19. On Catoptrics : 1710.
20. On the Monochord ; in the Machines, tom. 1, with some other pieces, not mathematical.

CARRIAGE, of a Cannon, is the machine upon which it is mounted; serving to point or direct it for firing, and to convey it from place to place.

Wheel CARRIAGE, one that is mounted and moved about upon wheels. Horses draw in general, to most advantage, when the direction of their draft is parallel to the ground, or rather a little upwards. A carriage also goes easiest when the centre of gravity is placed very high; since, when once put in motion, it continues it with very little labour to the horses.

CARTES (RENE DES), one of the most eminent philosophers and mathematicians of the 17th century, or indeed of any age whatever. He was descended of an ancient noble family in Touraine in France, being a younger son of a counsellor in the parliament of Rennes, and was born March 31, 1596. His father gave him a liberal education, and the more so as he observed in him the appearance of a promising genius, using to call him the Philosopher, on account of his insatiable curiosity in asking the reasons of every thing that he did not understand.

He soon made a remarkable progress in his studies, and from his infancy showed a decided taste for natural and philosophical knowledge. Disgusted with the jargon of an absurd philosophy, he found only in mathematics the certainty with which he was charmed. He gave himself up chiefly to this science, and thence he derived the most solid and indisputable part of his renown. Yet this philosopher, who taught others to think, who broke the yoke of antiquity, and re-established reason on her throne, this very Des Cartes, was himself led astray by his imagination. Let us respect his errors; for never did an ordinary man fall into the like. His edifice of Vortices, like the philosophy of Aristotle, has been demolished by the efforts of his successors; though his system concerning the nature of animals, in which he saw no principle superior to mecha-

nism, still divides the literary world. But if we do not always find truth in the works of Des Cartes, we are at no loss to trace evident marks of genius. That philosopher was a profound thinker, and spent his life in solitude. In vain did Cardinal Richelieu, in the name of the king, offer him important posts: he preferred his retirement to the slavery of honours. Yet, yielding to the urgent solicitations of Queen Christina of Sweden, who wished to see and converse with him, he repaired to Stockholm. But the hours of their interviews were not regulated by the habits of Des Cartes, nor congenial to his nature. That great man, born with a weak constitution, which was rendered still more delicate by his custom of meditating in bed, could not long sustain the task of rising every morning at five o'clock, in the winter rigours of a northern climate, to repair to the library of Christina. A defunction on the lungs terminated his life on the 11th of February, 1650. In 1667, his corpse was conveyed to France, and is now deposited in the Pantheon at Paris.

"Nature," says Voltaire, "had favoured Des Cartes with a strong and clear imagination, whence he became a very singular person, both in private life and in his manner of reasoning. This imagination could not be concealed even in his philosophical writings, which are every where adorned with very brilliant ingenious metaphors. Nature had almost made him a poet; and indeed he wrote a piece of poetry for the entertainment of Christina, queen of Sweden, which however was suppressed in honour of his memory. He extended the limits of geometry as far beyond the place where he found them, as Newton did after him; and first taught the method of expressing curves by equations. He applied this geometrical and inventive genius to dioptrics, which when treated by him became a new art; and if he was mistaken in some things, the reason is, that a man who discovers a new tract of land, cannot at once know all the properties of the soil. Those who come after him, and make these lands fruitful, are at least obliged to him for the discovery." Voltaire acknowledges, that there are innumerable errors in the rest of Des Cartes's works; but adds, that geometry was a guide which he himself had in some measure formed, and which would have safely conducted him through the several paths of natural philosophy: yet he had at last abandoned this guide, and gave entirely into the humour of framing hypotheses; and then philosophy was no more than an ingenious romance, fit only to amuse the ignorant.

It has been pretty generally acknowledged, that he borrowed his improvements in algebra from Harriot's *Artis Analyticae Praxis*; which is highly probable, as he was in England about the time when Harriot's book was published, and follows the manner of Harriot, except in the method of noting the powers. On this head the following anecdote is related by Dr. Pell, in Wallis's *Algebra*, pa. 198. Sir Charles Cavendish, then resident in Paris, discoursing there with M. Roberval, concerning Des Cartes' Geometry, then lately published: I admire, said Roberval, that method in Des Cartes, of placing all the terms of the equation on one side, making the whole equal to nothing, and how he fell upon it. The reason why you admire it, said Sir Charles, is because you are a Frenchman; for if you were an Englishman, you would not admire it. Why so? asked Roberval. Because, replied Sir Charles, we in England know whence he had it; namely, from Harriot's *Algebra*. What book is that? says Roberval; I never saw it. Next time you come to my chamber, said Sir Charles,

I will show it to you. Which a while after he did: and on perusal of it, Roberval exclaimed with admiration, *Il l'a vu! il l'a vu!* *He had seen it! he had seen it!* finding all that in Harriot which he had before admired in Des Cartes, and not doubting but that Des Cartes had it from thence. See also Montucla's *History of Mathematics*.

The real improvement of Des Cartes in algebra and geometry, I have particularly treated of under the article *ALGEBRA*; and his philosophical doctrines are displayed in the article *CARTESIAN Philosophy*, here following. He was never married, but had one natural daughter, who died when she was five years old. There have been several editions of his works, and commentaries upon them; particularly those of Schooten on his *Geometry*.

CARTESIAN Philosophy, or *Cartesianism*, the system of philosophy advanced by Des Cartes, and maintained by his followers, the *Cartesians*.

The Cartesian philosophy is founded on two great principles, the one metaphysical, the other physical. The metaphysical one is this: I think, therefore I am, or I exist: the physical principle is, that nothing exists but substances. Substance he makes of two kinds; the one a substance that thinks, the other a substance extended: so that actual thought and actual extension make the essence of substance.

The essence of matter being thus fixed in extension, Des Cartes concludes that there is no vacuum, nor any possibility of it in nature; but that the universe is absolutely full: by this principle, mere space is quite excluded; for extension being implied in the idea of space, matter is so too.

Des Cartes defines motion to be the translation of a body from the neighbourhood of others that are in contact with it, and considered as at rest, to the neighbourhood of other bodies: by which he destroys the distinction between motion that is absolute or real, and that which is relative or apparent. He maintains that the same quantity of motion is always preserved in the universe, because God must be supposed to act in the most constant and immutable manner. And hence also he deduces his three laws of motion. See *MOTION*.

On these principles, Des Cartes explains mechanically how the world was formed, and how the present phenomena of nature came to arise. He supposes that God created matter of an indefinite extension, which he separated into small cubic portions or masses, full of angles: that he impressed two motions on this matter; the one, by which each part revolved about its own centre; and another, by which an assemblage, or system of them, turned round a common centre. From whence arose as many different vortices, or eddies, as there were different masses of matter, thus moving about common centres.

The consequence of these motions in each vortex, according to Des Cartes, is as follows: The parts of matter could not thus move and revolve among one another, without having their angles gradually broken; and this continual friction of parts and angles must produce three elements: the first of these, an infinitely fine dust, formed of the angles broken off; the second, the spheres remaining, after all the angular parts are thus removed; and those particles not yet rendered smooth and spherical, but still retaining some of their angles, and hannonous parts, form the third element.

Now the first or subtlest element, according to the laws of motion, must occupy the centre of each system, or vor-

tex, by reason of the smallness of its parts: and this is the matter which constitutes the sun, with the fixed stars above, and the fire below. The second element, made up of spheres, forms the atmosphere, and all the matter between the earth and the fixed stars; in such sort, that the largest spheres are always next the circumference of the vortex, and the smallest next its centre. The third element, formed of the irregular particles, is the matter that composes the earth, and all terrestrial bodies, together with comets, spots in the sun, &c.

He accounts for the gravity of terrestrial bodies from the centrifugal force of the æther revolving round the earth: and on the same general principles he pretends to explain the phenomena of the magnet, and to account for all the other operations in nature.

The Cartesian system has received many alterations and amendments; ingeniuous men, for full a century, employing their talents in reforming one part, and new-modelling another; but it is now generally acknowledged that the foundation was faulty, and the superstructure erroneous; so that the fabric, though allowed to be a work of genius, is abandoned to neglect and ruin, and is pointed at as a memorial of philosophical presumption.

CARTOUCHE, in the Military Art, a case of wood, about 3 inches thick at the bottom, girt with marlin, holding about 400 musket balls, besides 6 or 8 balls of iron of a pound weight, to be fired from howitzers for the defence of a pass, &c.

CARTRIDGE, in the Military Art, the charge or load of a fire-arm, wrapped up in a thick paper, pasteboard, or parchment, to be the more readily charged, or conveyed into the piece. Cartridges of cannon and mortars are usually in cases of pasteboard, or tin, sometimes of wood half a foot long; taking up the place of the bullet in the piece to whose caliber the diameter is proportioned. Those of muskets, pistols, and small-arms, only contain the charge of powder, with a ball wrapped up in thick paper.

Flannel cartridges are now preferred, because they do not retain the fire, and are therefore less liable to accidents in loading. A parchment cap is made to cover them, in order to prevent the dust of powder from passing through them, which is taken off before they are put into the piece.

CARTRIDGE-BOX, a case of wood or turned iron, covered with leather, holding a dozen musket-cartridges. It is worn upon a belt, and hangs a little lower than the right pocket-hole.

CARY (ROBERT), a learned English chronologer and divine, was born at Cockington, in the county of Devon, about the year 1615. He took his degrees in arts, and L.L. D. in Oxford. After returning from his travels he was presented to the rectory of Plymouth, near Kingsbridge in Devonshire: but not long after he was drawn over by the presbyterian ministers to their party, and chosen moderator in that part of the second division of the county of Devon, which was appointed to meet at Kingsbridge. And yet, on the restoration of Charles the 2d, he was one of the first to congratulate that prince on his return, and soon after was preferred to the archdeaconry of Exeter; but from which he was however some time afterward ejected. The remainder of his days he spent at his rectory at Plymouth, and died in 1688, at 73 years of age.—He published *Palæologia Chronica*, a chronological account of ancient time, in three parts: 1, Didactical; 2, Apodidactical; 3, Canonical: in 1677.

CASATI (PAUL), a learned Jesuit, born at Placentia in 1617. He entered early among the Jesuits; and after having taught mathematics and divinity at Rome, he was sent into Sweden to Queen Christina, whom he prevailed on to embrace the popish religion. His writings are as follow:

1. *Vacuum Proscriptum*.—2. *Terra Machinis mota*.—3. *Mechanicorum, libri octo*.—4. *De Igne Dissertationes*.—5. *De Angelis Disputatio Theolog.*—6. *Hydrostaticæ Dissertationes*.—7. *Opticæ Disputationes*. It is remarkable that he wrote this treatise on optics at 88 years of age, and after he was blind. He was also author of several books in the Italian language.

CASCABEL, the knob or button of metal behind the breech of a cannon, serving as a kind of handle by which to elevate and direct the piece; to which some add the fillet and ogees as far as the base-ring.

CASEMATE, or CAZEMATE, in Fortification, a kind of vault or arch, of stone-work, in that part of the flank of a bastion next the curtain; serving as a battery, to defend the face of the opposite bastion.

It is now seldom used, because the batteries of the enemy are apt to bury the artillery of the casemate in the ruins of the vault: beside, the great smoke made by the discharge of the cannon, renders it intolerable to the men. So that, instead of the ancient covered casemates, later engineers have contrived open ones, only guarded by a parapet, &c.

CASEMATE, or CASEMENT, in Architecture, a hollow moulding, which some architects make $\frac{1}{2}$ of a circle, and others $\frac{1}{4}$. Casement is also used for a small moveable window, usually within a larger, being made open to turn on hinges.

CASERNS, or CAZERNS, in Fortification, small rooms, or huts, erected between the ramparts and the houses of fortified towns, or even on the ramparts themselves; to serve as lodgings for the soldiers on immediate duty, to ease the garrison.

CASE-SHOT, or CANNISTER-SHOT, are a number of small balls put into a round tin cannister, and so shot out of great guns. These have superseded, and been substituted instead of, the grape-shot, which have been laid aside.

CASSINI (JOHN-DOMINIC), an eminent astronomer, was born of noble parents, at a town in Piedmont in Italy, June 8, 1625. After laying a proper foundation in his studies at home, he was sent to continue them in a college of Jesuits at Genoa. He had an uncommon turn for Latin poetry, which he exercised so very early, that some of his poems were published when he was but 11 years old. At length he met with books of astronomy, which he read with great eagerness. Pursuing the bent of his inclinations in this way, he soon acquired a very extensive knowledge of the subject, and in 1650 the senate of Bologna invited him to be their public mathematical professor. Cassini was but 25 years of age when he went to Bologna, where he taught mathematics, and made celestial observations with great care and assiduity.—In 1652 a comet appeared, which he observed with great accuracy; and he discovered that comets were not bodies accidentally generated in the atmosphere, as had been supposed, but of the same nature, and probably governed by the same laws, as the planets. The same year he resolved an astronomical problem, which Kepler and Bulliald had given up as insolvable; viz, to determine geometrically the apogee and eccentricity of a planet, from its true and mean place.—

In 1653, when a church in Bologna was repaired and enlarged, he obtained leave of the senate to correct and settle a meridian line, which had been drawn by an astronomer in 1575.—In 1657 he attended, as an assistant, a nobleman, who was sent to Rome to compose some differences, which had arisen between Bologna and Ferrara, from the inundations of the Po; and he showed so much skill and judgment in the management of the affair, that in 1663 the pope's brother appointed him inspector general of the fortifications of the castle of Urbino: and he had afterwards committed to him the care of all the rivers in the ecclesiastical state.

Meanwhile he did not neglect his astronomical studies, but cultivated them with great care. He made several discoveries relative to the planets Mars and Venus, particularly the revolution of Mars about his axis: but the point he had chiefly in view, was to settle an accurate theory of Jupiter's satellites; which, after much labour and observation, he happily effected, and published it at Rome, among other astronomical pieces, in 1666.

Picard, the French astronomer, getting Cassini's tables of Jupiter's satellites, found them so very exact, that he conceived the highest opinion of his skill; and from that time his fame increased so fast in France, that the government desired to have him a member of the Academy. Cassini however could not quit his station without leave of his superiors; and therefore the king, Lewis the 14th, requested of the pope and the senate of Bologna, that Cassini might be permitted to come into France. Leave was granted for 6 years; and he came to Paris in the beginning of 1669, where he was immediately made the king's astronomer. When this term of 6 years was nearly expired, the pope and the senate of Bologna insisted on his return, on pain of forfeiting his revenues and emoluments, which had hitherto been faithfully remitted to him: but the minister Colbert notwithstanding prevailed on him to stay, and he was naturalized in 1673; the year in which he was married.

The Royal Observatory of Paris had been finished some time. The occasion of its being built was this: In 1638, the celebrated Mersenne was the chief institutor and promoter of a society, where several ingenious and learned men met together to talk upon physical and astronomical subjects; among whom were Gassendi, Descartes, Monmort, Thevenot, Bulliald, our countryman Hobbes, &c: and this society was kept up by a succession of learned men for many years. At length the government considering that a number of such men, acting in a body, would succeed much better in the promotion of science, than if they acted separately, each in his particular art or province, established under the direction of Colbert, in 1666, the Royal Academy of Sciences: and for the advancement of astronomy in particular, erected the Royal Observatory at Paris, and furnished it with all kinds of instruments that were necessary to make observations. The foundation of this noble pile was laid in 1667, and the building completed in 1670. Of this observatory, Cassini was appointed the first inhabitant; which he took possession of in Sept. 1671. In 1672 he endeavoured to determine the parallax of Mars and the sun: and in 1677 he proved that the diurnal rotation of Jupiter about his axis was performed in 9 hours 58 minutes, from the motion of a spot in one of his larger belts: also in 1684 he discovered four satellites of Saturn, besides that which Huygens had observed. In 1693 he published a new edition of his Tables

of Jupiter's Satellites, corrected by later observations. In 1695 he took a journey to Bologna, to examine the meridian line, which he had fixed there in 1655; and he showed, in the presence of eminent mathematicians, that it had not varied in the least, during that 40 years. In 1700 he continued the meridian line through France, which Picard had begun, to the very southern limits of that country.

Our author resided at the royal observatory for more than 40 years, making many excellent and useful discoveries. The titles of his publications occupy nearly 5 pages in the closely printed index of Rozier, and consequently far exceed our bounds even to enumerate in this place. He had the misfortune in his latter years to be deprived of his sight; and he ended a useful and honourable life September 14th 1712, at the age of 87 years.

CASSINI (JAMES), a celebrated French astronomer, and member of the several Academies of Sciences of France, England, Prussia, and Bologna, was born at Paris, Feb. 18, 1677, being the younger son of John-Dominic Cassini, above mentioned, whom he succeeded as astronomer at the royal observatory, the elder son having lost his life at the battle of La Hogue.

After his first studies in his father's house, in which it is not to be supposed that mathematics and astronomy were neglected, he was sent to study philosophy at the Mazarine college, where the celebrated Varignon was then professor of mathematics; from whose assistance young Cassini profited so well, that at 15 years of age he supported a mathematical thesis with great honour. At the age of 17 he was admitted a member of the Academy of Sciences; and the same year he accompanied his father in his journey to Italy, where he assisted him in the verification of the meridian at Bologna, and other measurements. On his return he made other similar operations in a journey into Holland, where he discovered some errors in the measure of the earth by Snell, the result of which was communicated to the Academy in 1702. He also visited England in 1696, where he was made a member of the Royal Society.—In 1712 he succeeded his father as astronomer royal at the observatory.—In 1717 he gave to the Academy his researches on the distance of the fixed stars, in which he showed that the whole annual orbit, of near 200 millions of miles diameter, is but as a point in comparison of this distance. The same year he communicated also his discoveries concerning the inclination of the orbits of the satellites in general, and especially of those of Saturn's satellites and ring.—In 1725 he undertook to determine the cause of the moon's libration.

In 1732 an important question in astronomy exercised the ingenuity of our author. His father had determined, by his observations, that the planet Venus made one complete revolution about her axis in 23 hours: and M. Bianchini had published a work in 1729, in which he settled the period of the same revolution at 24 days 8 hours. From an examination of Bianchini's observations, which were upon the spots in Venus, he discovered that he had intermitted his observations for the duration of 3 hours, from which cause he had probably mistaken new spots for the old ones, and so had been led into the mistake. He soon afterwards determined the nature and quantity of the acceleration of the motion of Jupiter, at half a second per year, and of that of the retardation of Saturn at two minutes per year; that these quantities would go on increasing for 2000 years, and then would decrease again.—In

1740 he published his Astronomical Tables; and his Elements of Astronomy; both of which are very extensive and accurate works.

Though astronomy was the principal object of our author's consideration, he did not confine himself absolutely to that branch, but made occasional excursions into other fields. We owe also to him, for example, Experiments on Electricity, on the light produced by friction; Experiments on the recoil of fire-arms; Researches on the rise of the mercury in the barometer at different heights above the level of the sea; Reflections on the perfecting of burning-glasses; and other memoirs.

The French Academy had properly judged that one of its most important objects, was the measurement of the earth. In 1669 Picard measured a little more than a degree of latitude to the north of Paris; but as that extent appeared too small from which to conclude the whole circumference with sufficient accuracy, it was resolved to continue that measurement on the meridian of Paris to the north and south, through the whole extent of the country. Accordingly, in 1683, M. Lahire continued that on the north side of Paris, and the elder Cassini that on the south side. The latter was assisted in 1700 in the continuation of this operation by his son James. The same work was farther continued by the same Academicians; and finally the part left unfinished by Lahire in the north, was finished in 1718 by our author, with the late Maraldi, and Lahire the younger.

These operations produced a considerable degree of precision. It appeared also, from this measured extent of 6 degrees, that the degrees were of different lengths in different parts of the meridian; and in such sort that our author concluded, in the volume published for 1718, that they decreased more and more towards the pole, and that therefore the figure of the earth was that of an oblong spheroid, having its axis longer than the equatorial diameter. He also measured the perpendicular to the same meridian, and compared the measured distance with the differences of longitude, as before determined by the eclipses of Jupiter's satellites; whence he inferred, that the length of the degrees of longitude was smaller than it would be on a sphere, and that therefore again the figure of the earth was an oblong spheroid; contrary to the determination of Newton by the theory of gravity. In consequence of these assertions of our author, the French government sent two different classes of mathematicians, the one to measure a degree at the equator, and the other at the polar circle; and the comparison of the whole determined the figure to be an oblate spheroid, contrary to Cassini's determination.

After a long and laborious life, our author James Cassini lost his life by a fall in April 1756, in the 80th year of his age, and was succeeded in the Academy and Observatory by his second son Cesar-François de Thury. He published A Treatise on the Magnitude and Figure of the Earth; as also The Elements or Theory of the Planets, with tables; besides a great number of papers in the Memoirs of the Academy, from the year 1699 to 1755.

CASSINI DE THURY (CESAR-FRANÇOIS), a celebrated French astronomer, director of the observatory, and member of most of the learned societies of Europe; was born at Paris June 17, 1714, being the second son of James Cassini, whose occupations and talents our author inherited and supported with great honour. He received his first lessons in astronomy and mathematics from MM. Ma-

raldi and Camus; and his progress was so great, that at 10 years of age he was able to calculate the phases of the total eclipse of the sun of 1727. At the age of 18 he accompanied his father in his two journeys undertaken for drawing the perpendicular to the observatory meridian, from Strasbourg to Brest. From that time a general chart of France was devised; for which purpose it was necessary to traverse the country by several lines, parallel and perpendicular to the meridian of Paris, and our author was intrusted with this business. He did not content himself with the measure of a degree by Picard; suspecting even that the measures which had been taken by his father and grandfather were not exempt from some errors the imperfections of their instruments at least would be liable to, he again undertook to measure the meridian at Paris, by means of a new series of triangles, of a smaller number, and more advantageously disposed. This great work was published in 1740, with a chart showing the new meridian of Paris, by two different series of triangles, passing along the sea-coasts to Bayonne, traversing the frontiers of Spain to the Mediterranean and Antibes, and thence along the eastern limits of France to Dunkirk, with parallel and perpendicular lines described at the distance of 6000 toises from one another, from side to side of the country.—In 1735 he had been received into the academy as adjoint supernumerary at 21 years of age.

A tour which our author made in Flanders, in company with the king, about 1741, gave rise to the particular chart of France, at the instance of the king. Cassini published different works relative to these charts, and a great number of the sheets of the charts themselves.

In 1761 Cassini undertook an expedition into Germany, for the purpose of continuing to Vienna the perpendicular of the Paris meridian; to unite the triangles of the chart of France with the points taken in Germany; to prepare the means of extending into this country the same plan as in France; and thus to establish successively for all Europe a most useful uniformity. Our author was at Vienna the 6th of June 1761, the day of the transit of Venus over the sun, of which he observed as much as the state of the weather would permit him to do, and published the account thereof in his Voyage en Allemagne.

Finally, M. Cassini, always meditating the perfection of his grand design, proposed at the peace between England and France in 1783, the joining of certain points taken upon the English coast with those which had been determined on the coast of France, and thus to connect the general chart of the latter with that of the British isles, like as he had before united it with those of Flanders and Germany. The proposal was favourably received by the English government, and presently carried into effect, under the direction of the Royal Society, the execution being committed to the late General Roy; after whose death the business was for some time suspended; but it was afterwards revived under the auspices of the Duke of Richmond, Master-General of the Ordnance, and the execution committed to the care of Col. Edward Williams and Captain (now Col.) William Mudge, both respectable officers of the Artillery, and Mr. Isaac Dalby, who had before accompanied and assisted General Roy; from whose united skill and zeal the happiest prosecution of this business was to be expected; as it has since been most ably completed by Col. Mudge, now Lieut. Governor of the Royal Military Academy; where as a cadet he received his mathematical education under the direction of the author of this Dictionary.

The volumes of the Memoirs of the French Academy for the years between 1735 and 1770 contain a prodigious number of papers by Cassini. They consist chiefly of astronomical observations and questions; among which are, Researches concerning the parallax of the sun, the moon, Mars, and Venus; On astronomical refractions, and the effect caused in their quantity and laws by the weather; Numerous observations on the obliquity of the ecliptic, and on the law of its variations. In short, he cultivated astronomy for 50 years, a period the most important for that science that ever elapsed, for the magnitude and variety of objects, in which he commonly sustained a considerable share.

M. Cassini was of a very strong and vigorous constitution, which carried him through the many laborious operations in geography and astronomy which he conducted. An habitual retention of urine however rendered the last 12 years of his life very painful and distressing, till it was at length terminated by the small-pox the 4th of September 1784, in the 71st year of his age; being succeeded in the academy, and as director of the observatory, by his only son Count John-Dominic Cassini; who is the 4th in order by direct descent in that honourable station.

CASSIOPEIA, one of the 48 old constellations, placed near Cepheus, not far from the north pole. The Greeks probably received this figure, as they did the rest, from the Egyptians, and in their fables added it to the family in the neighbouring part of the heavens, making her the wife of Cepheus, and mother of Andromeda. They pretend that she was placed in this situation, to behold the destruction of her favourite daughter Andromeda, who is chained just by her on the shore, to be devoured; and this as a punishment for her pride and vanity in presuming to stand the comparison of beauty with the Nereids.

In the year 1572 there burst out all at once in this constellation a new star, which at first surpassed Jupiter himself in magnitude and brightness; but it diminished by degrees, till it quite disappeared at the end of 18 months. This star alarmed all the astronomers of that age, many of whom wrote dissertations upon it; among the rest Tycho Brahé, Kepler, Maurolycus, Lycetus, Gramineus, and others. Beza, the Landgrave of Hesse, Rosa, and some more, wrote to prove it a comet, and the same that appeared to the Magi at the birth of Christ, and that it came to declare his second coming: these were answered by Tycho.

The stars in the constellation of Cassiopeia, are in Ptolemy's Catalogue 13, in Hevelius's 37, in Tycho's 46, and in Flamsteed's 55.

CASTELLI (BENEDICT ABBATE), an eminent mathematician, was born of an ancient and noble family at Brescia, in the year 1577. In 1595 he entered into a monastery of the order of St. Benedict, in his native city. He was for some time a disciple of Galileo at Florence, and assisted him in his astronomical observations, and afterwards maintained a regular correspondence with him. Under his name, the apology of Galileo against the censures of Ludovico delle Colombe and Vincent di Grazia appeared, though it was principally written by Galileo himself. From 1615 to 1625 he occupied the mathematical chair at Pisa. In 1625 Castelli was invited to Rome by Pope Urban VIII, and made mathematical professor in the college della Sapienza. The subject of his particular attention, and in the investigation of which he chiefly excelled, was the motion of water; and in 1628 he published two works upon it,

Vol. I.

which gained much reputation; viz, The Mensuration of running waters, and Geometrical Demonstrations of the mensuration of running waters. These have been lately inserted in the collection of the author's works on similar topics, printed at Florence, with other treatises on the lagoon of Venice, on the improvement of the Pontine, Bollognese, Ferrarese, and Romagnese marshes, &c. Guglielmini, though in other things he impugns Castelli, allows him the honour of having first applied geometry to the motion of water; and Montucla (Hist. Math. t. 2, p. 201) calls him "The creator of a new part of hydraulics." He died at Rome in 1644.

CASTOR, a moiety of the constellation Gemini; called also Apollo. Also a star in this constellation, whose latitude, for the year 1700, according to Hevelius, was $10^{\circ} 4' 20''$ north; and its longitude $\gtrless 160^{\circ} 4' 14''$.

CASTOR and POLLUX. See GEMINI.

CASTOR and POLLUX, in Meteorology, is a fiery meteor, which at sea appears sometimes adhering to a part of the ship, in the form of a ball, or even several balls. When one is seen alone, it is properly called Helena; but two are called Castor and Pollux, and sometimes Tyndaridae.

By the Spaniards, Castor and Pollux are called San Elmo; by the French, St. Elme, St. Nicholas, St. Clare, St. Helene; by the Italians, Hermo; and by the Dutch, Vree Vuuren.

The meteor Castor and Pollux, it is commonly thought, denotes cessation of the storm, and a future calm; as it is rarely seen till the tempest is nearly spent. But Helena alone portends ill weather, and denotes the severest part of the storm yet behind.

When the meteor adheres to the masts, yards, &c, it is concluded, from the air not having motion enough to disipate this flame, that a profound calm is at hand; but if it flutter about, that it denotes a storm.

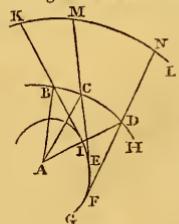

CASTRAMETATION, the art, or act, of encamping an army.

CATACAUSTICS, or *Catacaustic Curves*, in the Higher Geometry, and in Optics, are the species of caustic curves formed by reflection. These curves are generated after the following manner: If there be an infinite number of rays AB , AC , AD , &c, proceeding from the radiating point A , and reflected at any given curve $BEDH$, so that the angles of incidence be still equal to the angles of reflection; then the curve BEG , to which the reflected rays BI , CE , DF , &c, are everywhere tangents, as at the points I , E , F , &c, is the catacaustic, or caustic-by-reflection.

Or it is the same thing as saying, that a caustic curve is that formed by joining the points of concurrence of the several reflected rays.

Some properties of these curves are as follow. If the reflected ray IB be produced to K , so that $AB = BK$, and the curve KL be the evolute of the caustic BEG , beginning at the point K ; then the portion of the caustic BE is $= (AC - AB) + (CE - BI)$, that is, the difference of the two incident rays added to the difference of the two reflected rays.

When the given curve BED is a geometrical one, the caustic will be so too, and will always be rectifiable. The

caustic of the circle is a cycloid, or epicycloid, formed by the revolution of a circle upon a circle.

Thus, ABD being a semi-circle, exposed to parallel rays; then those rays which fall near the axis CB will be reflected to F , the middle point of BC ; and those which fall at A , as they touch the curve only, will not be reflected at all; but any intermediate ray HJ will be reflected to a point K , somewhere between A and F . And since every different incident ray will have a different focal point, therefore those various focal points will form a curve line AEG in one quadrant, and FED in the other, being the cycloid above mentioned. The caustic of the common cycloid, when the rays are parallel to its axis, is also a common cycloid, described by the revolution of a circle on the same base. The caustic of the logarithmic spiral, is the same curve.

The catacaustic may be beautifully exhibited experimentally by exposing the inside of a smooth bowl, or glass, to the sun-beams, or strong candle-light; for then this curve $AEGFD$ will appear plainly delineated on any white surface placed horizontally within the same, as on the surface of milk contained in the bowl.

The principal writers on the caustics are, l'Hôpital, Carré, &c. See Mémoires de l'Acad. an. 1666 & 1703.

CATACOUSTICS, or *Cauphonics*, is the science of reflected sounds; or that part of acoustics which treats of the properties of echoes.

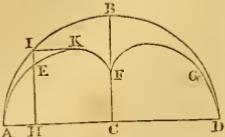

CATACOUSTICS, in Military Language, are écoutes or small galleries, from distance to distance, in front of the glacis of a fortified place, all of which communicate with a gallery that is carried parallel to the covert-way. The besieged make use of them in going to meet the enemy's miners, and interrupt their progress.

CATADIOPTRICAL Telescope, the same as Reflecting Telescope; which see.

CATALOGUE of the Stars, is a list of the fixed stars, disposed according to some order, in their several constellations; with the longitudes, latitudes, right ascensions, &c. of each.

Catalogues of the stars have usually been disposed, either as collected into certain figures called constellations, or according to their right ascensions, that is the order of their passing over the meridian. All the catalogues, from the most ancient down to Flamsteed's inclusively, were of the first of these forms, or in constellations; but most of the others that have since appeared are of the latter form, as being much more convenient for most purposes. Indeed one has lately been constructed in which the stars are disposed in classes according to zones or degrees of polar distance.

Hipparchus of Rhodes first undertook to make a catalogue of the stars, about 128 years before Christ; in which he made use of the observations of Timocharis and Aristyllius, for about 140 years before him. Ptolemy retained Hipparchus's catalogue, containing 1026 fixed stars in 48 constellations, though he himself made abundance of observations, with a view to a new catalogue, an. Dom. 140 Albategni, a Syrian, brought the same down to his own time, viz. about the year of Christ 880. Anno 1437, Ulugh Begh, or Beg, king of Parthia and India, formed a new

catalogue of 1022 fixed stars, or according to some 1016; since translated out of Persian into Latin by Dr. Hyde, in 1665. The third person who made a catalogue of stars from his own observations was Tycho Brahe, who determined the places of 777 stars, for the end of the year 1600; which Kepler, from other observations of Tycho, afterwards increased to the number of 1000 in the Rudolphine tables; adding those of Ptolemy and other authors, omitted by Tycho; so that his catalogue amounts to above 1160. About the same time, William landgrave of Hesse, with his mathematicians Byrgius and Rothman, determined the places of 400 stars from new observations, rectifying them for the year 1593; which Hevelius prefers to those of Tycho. Riccioli, in his *Astronomia Reformata*, determined the places of 101 stars for the year 1700, from his own observations: for the rest, he followed Tycho's catalogue; altering it where he thought proper. Anno 1667 Dr. Halley, in the island of St. Helena, observed 350 of the southern stars, not visible in our horizon. The same labour was repeated by Father Noel in 1710, who published a new catalogue of the same stars constructed for the year 1687. Also De la Caille, at the Cape of Good Hope, made accurate observations of about 10 thousand stars near the south pole, in the years 1751 and 1752; the catalogue of which was published in the *Mémoirs of the French Academy of Sciences* for the year 1752, and in some of his own works, as more particularly noticed below.

Bayer, in his *Uranometria*, published in 1603 a catalogue of 1160 stars, compiled chiefly from Ptolemy and Tycho, in which every star is marked with some letter of the Greek alphabet; the brightest or principal star in any constellation being denoted by the first letter of the alphabet, the next star in order by the second letter; and so on; and when the number of stars exceeds the Greek alphabet, the remaining stars are marked by the letters of the Roman alphabet; which letters are preserved by Flamsteed in his catalogue, and also by Senex on his globes, and indeed by most astronomers since that time.

In 1673, the celebrated John Hevelius, of Dantzig, published, in his *Machina Coelestis*, a catalogue of 1888 stars, of which 1553 were observed by himself; and their places set down for the end of the year 1660. But this catalogue, as it stands in Flamsteed's *Historia Coelestis* of 1725, contains only 1520 stars.

The most complete catalogue ever given from the labours of one man, was the *Britannic catalogue*, compiled from the observations of the accurate and indefatigable Mr. Flamsteed, the first Royal Astronomer at Greenwich; who for a long series of years devoted himself wholly to that employment. As there was nothing wanting, either in the observer or apparatus, this may be considered as a perfect work, so far as it goes. It is however to be regretted that the edition did not pass through his own hands: that now extant was published by authority, but without the author's consent, and contains 2734 stars. Another edition was published in 1725, pursuant to his testament, containing 3000 stars, with their places adapted to the beginning of the year 1689; to which is added Mr. Sharp's catalogue of the southern stars not visible in our hemisphere, set down for the year 1726. See vol. 3 of his *Historia Coelestis*, in which are printed the catalogues of Ptolemy, Ulugh Begh, Tycho, the Prince of Hesse, and Hevelius; with an account of each of them in the *Prolegomena*.

The first catalogue, we believe, that was printed in the new or second form, according to the order of the right ascensions, is that of Lacaille, given in his *Ephemerides for the 10 years between 1755 and 1765*, and printed in 1755. It contains the right ascensions and declinations of 307 stars, which are rectified to the beginning of the year 1750.—In 1757, Lacaille published his *Astroiomiae Fundamenta*, containing a catalogue of the right ascensions and declinations of 398 stars, likewise adapted to the beginning of 1750.—And in 1763, the year after his death, was published the *Coelum Australis Stelliferum* of the same author; containing a catalogue of the places of 1942 stars, all situated to the southward of the tropic of Capricorn, and observed by him while he was at the Cape of Good Hope, in 1751 and 1752; their places being also suited to the beginning of 1750.—In the same year was published his *Ephemerides for the 10 years between 1765 and 1775*; in the introduction to which are given the places of 515 zodiacal stars, all deduced from the observations of the same author; and adjusted to the beginning of the year 1765.

In the Nautical Almanac for 1773, is given a catalogue of 387 stars, in right ascension, declination, longitude, and latitude, derived from the observations of the late celebrated Dr. Bradley, and adapted to the beginning of the year 1760. This small catalogue, and the results of about 1200 observations of the moon, are all that the public have yet seen of the multiplied labours of this most accurate and indefatigable observer, though he has now (1814) been dead upwards of 52 years.

In 1775 was published a thin volume entitled¹ *Opera Inedita*, containing several papers of the late Tobias Mayer, and among them a catalogue of the right ascensions and declinations of 998 stars, which may be occulted by the moon and planets; the places being adjusted to the beginning of the year 1756.

At the end of the first volume of *Astronomical Observations made at the Royal Observatory at Greenwich*, published in 1776, Dr. Maskelyne, the late Astronomer Royal, gave a catalogue of the places of 34 principal stars, in right ascension and north-polar distance, adapted to the beginning of the year 1770. These being the result of several years' repeated observations, made with the utmost care and the best instruments, may be presumed to be exceedingly accurate.

In 1782, M. Bode, of Berlin, published a very extensive catalogue of 5058 of the fixed stars, collected from the observations of Flamsteed, Bradley, Hevelius, Mayer, Lacaille, Messier, Monnier, D'Arquier, and other astronomers; all rectified to the beginning of the year 1780; and accompanied with a Celestial Atlas, or sets of maps of the constellations, engraved in a most delicate and beautiful manner.

To these may be added, Dr. Herschel's catalogue of double stars, printed in the *Philos. Trans.* for 1782 and 1783; Messier's nebular and clusters of stars, published in the *Connoissance des Temps* for 1784; and Herschel's catalogue of the same kind, given in the *Philos. Trans.* for 1786, and other years.

In 1789, the Rev. Francis Wollaston published *A Specimen of a General Astronomical Catalogue, in Zones of North-polar Distance*, and adapted to Jan. 1, 1790. These stars are collected from all the catalogues before-mentioned, from that of Hevelius downwards. This work contains five distinct catalogues; viz., Dr. Maskelyne's

new catalogue of 36 principal stars; a general catalogue of all the stars, in zones of north-polar distance; an index to the general catalogue; a catalogue of all the stars, in the order in which they pass the meridian; and a catalogue of zodiacal stars, in longitude and latitude.

In 1792, Dr. Zach published at Gotha, *Tabulæ Motuum Solis*, to which is annexed a new catalogue of the principal fixed stars, from his own observations made in the years 1787, 1788, 1789, 1790. This catalogue contains the right ascensions and declinations of 381 principal stars, adapted to the beginning of the year 1800.

The catalogues of Dr. Bradley, Lacaille, Zach, and Mayer, are published by Professor Vince, in the second volume of his *Astronomy*. M. Lalande has published a new catalogue of more than 12,000 stars, in the volumes of the *Connoissance des Temps*, from the year 7 (1799) to the year 12. Almost all these are stars which had not been before observed. M. C. Vidal has lately communicated to the Lyceum of Toulouse a catalogue of 888 austral stars, from the 5th to the 7th magnitude inclusively: every star has been observed three times, and all are reduced to a mean position, regard being had to the effect of refraction, the aberration of light, and the rotation of the earth's axis. The mean position of all these stars has been calculated to a common period, viz. Jan. 31, 1798; the equation and precession of the equinoxes being previously allowed for. The place of M. Vidal's observations was Mirepoix, a situation admirably suited to his purpose, by the serenity of its atmosphere, and the excellence of the instruments with which the observatory is furnished, and commanding nearly six degrees of the heavens southwards more than Paris. On this account C. Lalande and his nephew C. François Lalande, in their grand work of completing a catalogue of 48,000 stars, engaged M. Vidal to form a catalogue of the austral stars, which he has executed with great success and admirable precision. From the history of astronomy for 1800 by Jerome de Lalande, it appears that M. F. Lalande has terminated the labour commenced August 5, 1789, and determined the places of 50,000 stars, from the pole to 2 or 3 degrees below the tropic of Capricorn. In 1800, S. Piazzi, of Palermo, published his large catalogue, of 5500 stars.

CATAPULT, *Catapulta*, a military engine, much used by the ancients for throwing huge stones, and sometimes large darts and javelins, 12, 15, or even 18 feet long, on the enemy. It is sometimes confounded with the *Balista*, which is more peculiarly adapted for throwing stones; some authors making them the same, and others different.

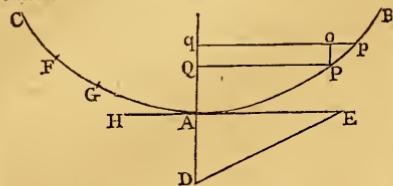

The catapult, which it is said was invented by the Syrians, consisted of two large timbers, like masts of ships, placed against each other, and bent by an engine for this purpose; these being suddenly unbent again by the stroke of a hammer, threw the javelins with prodigious force. Its structure and the manner of working it are described by Vitruvius; and a figure of it is also given by Perrault. M. Folard asserts that the catapult made infinitely more disorder in the ranks, than our cannon charged with iron balls. See Vitruv. Archit. lib. x. cap. 15 and 18; and Perr. notes on the same; also Rivius, p. 597.

Josephus takes notice of the surprising effects of these engines, and says, that the stones thrown out of them, of a hundred weight or more, beat down the battlements, knocked the angles off the towers, and would level a whole

file of men from one end to the other, if the phalanx were ever so deep.

See plate V, fig. 3 and 4, for two forms of the catapult, the one for throwing darts and javelins, the other for stones.

CATENARY, a curve line which a chain, cord, or such like, forms itself into, by hanging freely from two points of suspension, whether these be in the same horizontal line or not; as the curve BAC , formed by a heavy flexible line suspended by any two points c and B . It is otherwise called the *elastic curve*.

The nature of this curve was sought after by Galileo, who thought it was the same with the parabola; but though Jungius detected this mistake, its true nature was not discovered till the year 1691, in consequence of M. John Bernoulli having published it as a problem in the Acta Eruditorum, to the mathematicians of Europe. In 1697 Dr. David Gregory published an investigation of the properties before discovered by Bernoulli and Leibnitz; in which he asserts that an inverted catenary is the best figure for an arch of a bridge, &c. See Philos. Trans. abr. vol. 4; also Bernoulli Opera, vol. 1. pa. 48, and vol. 3, pa. 491; and Cotes's Harmon. Mensur. pa. 108.

The catenary is a curve of the mechanical kind, and cannot be expressed by a finite algebraical equation, in simple terms of its absciss and ordinate; but is easily expressed by means of fluxions: thus, if α be its axis perpendicular to the horizon, and PQ an ordinate parallel to the same, or perp. to α ; also pq another ordinate indefinitely near the former, and po parallel to AQ : then, a being some given or constant quantity, the fundamental property of the curve is this, viz. $po : op :: AP : a$, or $\dot{x} : \dot{y} :: z : a$; that is, the fluxion of the axis, is to the fluxion of the ordinate, as the length of the curve, is to the given quantity a ; where $x = \alpha_0$, $y = po$, and $z = AP$. This, and the other properties of the curve, will plainly appear from the following considerations: First, supposing the curve hung up by its two points B and C , against a perpendicular or upright wall: then, every lower part of the curve being kept in its position by the tension of that which is immediately above it, the lower parts of the curve will retain the same position unvaried, by whatever points it is suspended above; thus, if it were fixed to the wall by the point r , or g , &c, the whole curve CAB will remain just as it was; for the tensions at r and g have the same effect on the other parts of the curve, as when it is fixed by those points: and hence it follows that the tension of the curve at the point α_0 in the horizontal direction, is a constant quantity, whether the two legs or branches of the curve, on both sides of it, be longer or shorter; which constant tension at α let be denoted by the quantity a .

Now, because any portion of the curve, as AP , is kept in its position by three forces, viz., the tensions at its extremities A and P , and its own weight, of which the tension at A acts in the direction $\alpha_0 A$ or po , and the tension at P acts in the direction of rp , and the weight of the line

acts in the perpendicular direction op ; that is, the three forces which retain the curve AP in its position, act in the directions of the sides of the elementary triangle opr ; but, by the principles of mechanics, any three forces, keeping a body in equilibrio, are proportional to the three sides of a triangle drawn in the directions in which those forces act; therefore it follows, that the forces keeping AP in its position, viz, the tension at A , the tension at P , and the weight of AP , are respectively as op , pr , and op , that is,

But the tension at A is the constant quantity a , and the weight of the uniform curve AP may be expounded by its length z ; therefore it follows that $\dot{x} : \dot{y} :: z : a$; which was to be proved.

Also from this last proportion, by proper analogy, or similar combinations of the terms, there arises this other property, $\dot{x} : \sqrt{(\dot{x}\dot{x} + \dot{y}\dot{y})}$ or $\dot{z} : z : \sqrt{(aa + zz)}$, or $\dot{z}\dot{z} = \dot{x}\sqrt{(aa + zz)}$, or $\dot{x} = \sqrt{\frac{\dot{z}\dot{z}}{(aa + zz)}}$; and the fluents of these give $x = \sqrt{(a^2 + z^2)}$. But, at the vertex of the curve, where $x = 0$, and $z = 0$, this becomes $0 = \sqrt{(a^2 + 0)} = a$; and therefore, by correction, the true equation of the fluents is $x = \sqrt{(a^2 + z^2)} - a$, or $a + x = \sqrt{(a^2 + z^2)}$; and hence also $z = \sqrt{[(a + x)^2 - a^2]} = \sqrt{(2ax + x^2)}$, and $a = \frac{z^2 - x^2}{2x}$: either of which is the equation of the curve, in terms of the arc and its absciss; from this it appears that $a + x$ is the hypotenuse of a right-angled triangle, whose two legs are a and z . So that, if in qa and ad produced, there be taken $ad = a$, and $ad =$ the curve z or AP ; then will the hypotenuse de be $= a + x$ or dq . And hence, any two of these three, a , x , z , being given, the third is given also.

Again, from the first simple property, viz, $\dot{x} : \dot{y} :: z : a$, or $a\dot{x} = \dot{y}z$, by substituting the value of z above found, it becomes $a\dot{x} = \dot{y}\sqrt{(2ax + x^2)}$, or $\dot{y} = \frac{a\dot{x}}{\sqrt{(2ax + x^2)}}$; and the fluent of this equation is $y = 2a \times \text{hyp. log. of } [\sqrt{x + \sqrt{(2a + x)}}]$. But at the vertex of the curve, where $x = 0$ and $y = 0$, this becomes $0 = 2a \times \text{hyp. log. of } \sqrt{2a}$; therefore the correct fluent is $y = 2a \times \text{hyp. log. of } \frac{\sqrt{x} + \sqrt{(2a + x)}}{\sqrt{2a}}$; an equation to the curve also, in terms of x and y , but not in simple algebraic terms. This last equation however may be brought to much simpler terms in different ways; as first, by squaring the logarithmic quantity and dividing its coefficient by 2, then $y = a \times \text{hyp. log. of } \frac{a + x + \sqrt{(2ax + x^2)}}{a} = a \times \text{hyp. log. } \frac{a + x + z}{a}$; and 2dly, by multiplying both numerator and denominator by $\sqrt{(2a + x)} - \sqrt{x}$, then squaring the product, and dividing the coefficient by 2, which gives $y = a \times \text{hyp. log. } \frac{z + x}{\sqrt{(x^2 - x^2)}} = a \times \text{hyp. log. } \frac{(z + x)^2}{x^2 - x^2} = a \times \text{hyp. log. } \frac{z + x}{z - x}$.

The catenary is the evolute to the equitangential curve.

CATHETUS, in Geometry, a name by which the perpendicular leg of a right-angled triangle is sometimes called; or it is in general any line or radius falling perpendicular on another line or surface.

CATHETUS of Incidence, in Catoptrics, is a right line drawn from a radiant point, or point of incidence, perpendicular to the reflecting line, or plane of the speculum.

CATHETUS of Reflection, or of the Eye, a right line drawn from the eye, perpendicular to the plane of reflection.

CATHETUS, in Architecture, denotes the axis of a cp-

lumn, &c. In the Ionic capital, it signifies a line passing perpendicularly through the eye or centre of the volute.

CATOPTRICS, the science of reflex vision; or that part of optics which explains the laws and properties of light reflected from mirrors, or specula.

The first treatise extant on catoptrics, is that which was composed by Euclid: this was published in Latin in 1604 by John Pena; it is also contained in Herigon's Course of Mathematics, and in Gregory's edition of Euclid's works; though it is suspected by some that this piece was not the work of that great geometrician, notwithstanding it is ascribed to him by Proclus in lib. 2, and by Marinus in his Preface to Euclid's Data. Alhazen, an Arabian author, composed a large volume of optics about the year 1100, in which he treats pretty fully of catoptrics: and after him Vitello, a Polish writer, composed another about the year 1270. Tacquet, in his Optics, has very well demonstrated the chief propositions of plane and spherical speculums. And the same is very ably done by Dr. Barrow in his Optical Lectures. There are also Trabe's Catoptrics, David Gregory's Elements of Catoptrics, Wolfius's Elements of Catoptrics, and those of Dr. Smith, contained in his learned and very elaborate Treatise on Optics, and many others of less note.

As this subject is treated under the general term Optics, the less need be said of it here. The whole doctrine of catoptrics depends on this simple principle, that the angle of incidence is equal to the angle of reflection; that is, that the angle in which a ray of light falls upon any surface, called the angle of incidence, is equal to the angle in which it quits it, when reflected from it, called the angle of reflection; though it is sometimes defined, that the angles of incidence and reflection, are those which the incident and reflected rays make, not with the reflecting surface itself, but with a perpendicular to that surface, at the point of incidence, which are the complements to the others: but it matters not by what name these angles are called, as to the truth and principles of the science; since, if the angles are equal, their complements are also equal. This principle of the equality between the angles of incidence and reflection, is mere matter of experience, being a phenomenon that has always been observed to take place, in every case that has fallen under observation, as near at least as mechanical measurements can ascertain; and hence it is inferred that it is a universal law of nature, and to be considered as matter of fact in all cases. Thus, let AC be an incident ray, falling on the reflecting surface DE , and CB the reflected ray, also co perpendicular to DE ; then is the angle $ACD = BCE$, or the angle $ACO = BCO$.

Of this law in nature, viz, the equality between the angles of incidence and reflection, it is remarkable, that in this way, the length or route $AC + CB$, in a ray passing from any point A to another given point B , by being reflected from any surface DE , is the shortest possible, namely $AC + CB$ is shorter than the sum $AG + GB$, of any other two lines inflected at the line DE ; and hence also the passage of the ray from A to B is performed in a shorter time than if it had passed by any other way.

From this simple principle, and the common properties

of linear geometry, the chief phenomena of catoptrics are easily deduced, and are as follows:

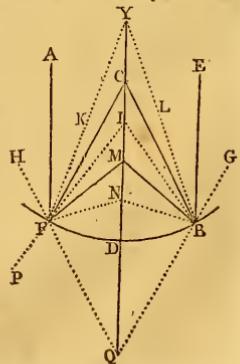

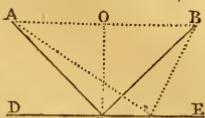

1. Rays of light reflected from a plane surface, have the same inclination to each other after reflection as they had before it. Thus, the rays AC, AI, AK , issuing from the radiant point A , and reflected by the surface DE into the lines CF, LI, KM ; these latter lines will have the same inclination to each other as the former AC, AI, AK , have. For draw ABG perpendicular to DE , and produce FC, LI, MK backwards to meet this perpendicular, so shall they all meet in the same point G , and AB will in every case be equal to BD : for the incident $\angle ACB$ is equal to the reflected $\angle FCE$, which is equal to the opposite angle BGC ; so that the two triangles ABC, BGC , have the angles at C equal, as also the right angles at B equal, and consequently the 3d angles at A and G equal; and having also the side BC common, they are equal in all respects, and $AB = BG$; and the same for the other rays: consequently the angles BGC, BGI, BGK , are respectively equal to the angles BAC, BAI, BAK ; that is, the reflected rays have the same inclinations as the incident ones have.

2. Hence it is that the image of an object, seen by reflection from a plain mirror, appears to proceed from a place G as far beyond, or on the other side of the reflecting plane DE , as the object A itself is before the plane. This is when the incident rays diverge from some point as A .

But if the case be reversed, and FC, LI, MK , be considered as incident rays, issuing from points F, I, M , and converging to some point G beyond the reflecting plane; then CA, IA, KA will become the reflected rays, and they will converge to the point A as far before the plane as the point G is beyond it.

So that universally, when the incident rays diverge from a point A , the reflected rays will also diverge from a point G ; and when the incident rays converge towards a point G , the reflected ones will also converge to a point A ; and in both cases these two points are at equal distances on the opposite sides of the reflecting plane DE .

3. Parallel rays reflected from a concave spherical surface, converge after reflection. For, let AE, CD, EB be three parallel rays falling on the concave surface FB , whose centre is C . To the centre draw the perpendiculars FC and BC ; also draw FM making the reflected angle, CFM , equal to the incident angle CFA ; and in like manner BM to make the angle $CBM = \angle CBE$; so shall the rays AF and EB be reflected into the converging rays FM and BM . As to the

ray CD , being perpendicular to the surface, it is reflected back again in the same line DC .

4. Converging rays falling on the concave surface are made to converge more. Thus, let GB and HF be the incident rays: then because the incident angle HFC is larger than the angle AFC , therefore the equal reflected angle NFC is greater than the reflected angle MFC , and so the point N is below the point M , or the line FN below the line FM ; in like manner BN is below BM ; that is, the reflected rays FN and BN are more converging in this case, than FM and BM in the other.

5. The focus to which all parallel rays, falling near the vertex D , are reflected, is in the middle of the radius MD . For, because the $\angle MFC = \angle AFC$, which is $=$ the alternate $\angle FCM$, therefore the sides opposite these angles are also equal, namely the side $FM = CM$; consequently, when the point F is very near the vertex D , then the sum $CM + MF$ is nearly $= CD$, and consequently CM nearly $= MD$, or the focus of the parallel rays is nearly in the middle of the radius. But the focus of other reflected rays is either above or below that of the parallel rays; namely, below when the incident rays are converging, and above when they are diverging; as is evident by inspection; thus, N the reflected focus of the converging rays GB and HF , is below M ; I that of the diverging rays YB and YF , is above M .

6. Incident and reflected rays are reciprocal, or so that if the reflected rays be returned back, or considered as incident ones, they will be reflected back into what were before their incident rays. And hence it follows that diverging rays, after reflection from a concave spherical surface, become either parallel or less diverging than before. Thus, the incident rays MF and MB are reflected into the parallel rays FA and BE , and the rays NF and NB are reflected into RH and RG , which are less diverging; also the rays YF and YB are reflected into FR and BL , which converge.—And hence all the phenomena of concave mirrors will be evident.

7. Rays reflected from a convex speculum, become quite contrary to those reflected from a concave one; so that the parallel rays become diverging, and the diverging rays become still more diverging; also converging rays will become either diverging, or parallel, or else less converging. Thus BDF being a spherical surface, whose centre is C , produce the radii CV and CFT which are perpendicular to the surface; then it is evident that the parallel rays AF and EB will be reflected into the diverging ones FK and BL ; and the diverging rays YB and YF become BO and FP which are more diverging; also the converging rays HF and GB become FR and BS which diverge, or else KF and LB become FA and BE which are parallel, or else lastly PF and ON become FY and BY which are converging.

8. Hence, as in the concave speculum, so also in the convex one, of parallel incident rays AF and EN , the imaginary focus M of their reflected rays FK and BL , is in

the middle of the radius when the speculum is a small segment of a sphere: but the reflected imaginary focus of other rays is either above or below the middle point M , viz N being that of the converging rays GB and HF , above M ; but I , that of the diverging rays YB and YF , above M .

9. When the speculum is the small segment of a sphere, either convex or concave, and the incident rays either converging or diverging, the distances of the foci, or points of concurrence, of the incident rays, and of the reflected rays, from the vertex of the speculum, are directly proportional to the distances of the same from the centre of it; that is, $YD : ID :: YC : IC$,
 $QD : ND :: QC : NC$.

For because the radius CF , or the same produced, bisects the angle YFI in the concave speculum, or the external angle YFP in the convex one, therefore $YF : IF :: YC : IC$; but when F is very near to D , then YF and IF become nearly YD and ID ; consequently $YD : ID :: YC : IC$.

In like manner, because CF bisects the angle QFN in the convex, or its external angle NFI in the concave speculum, therefore $QF : FN :: QC : IC$; but when F is very near to D , then QF and FN become nearly QD and ND ; and therefore $QD : ND :: QC : NC$.

For example, suppose it were required to find the focal distance of diverging rays incident on a convex surface, the radius of the sphere being 5 inches, and the distance of the radiant point from the surface 20 inches. Here then are given $YD = 20$, and $CD = 5$, to find ID : then the theorem

$$YD : ID :: YC : IC,$$

$$\text{in numbers } 20 : ID :: 25 : 5 - 1D,$$

$$\text{or by permutation } 20 : 25 :: ID : 5 - 1D,$$

$$\text{and by composition } 45 : 20 :: 5 : ID = \frac{180}{25} = \frac{36}{5} = 7\frac{1}{5}$$

$2\frac{1}{5}$ the focal distance sought.

And if it should happen in any case, that the value of ID in the calculation comes out a negative quantity, the focal distance must then be taken on the contrary side of the surface.

From the foregoing principles may be deduced and collected the following practical maxims, for plane and spherical mirrors, viz,

I. In a Plane Mirror.

(1.) The image will appear as far behind the mirror, as the object is before it.

(2.) The image will appear of the same size, and in the same position as the object.

(3.) Any plain mirror will reflect the image of an object of twice its own length and breadth.

II. In a Spherical Convex Mirror.

(1.) The image will always appear behind the mirror, or within the sphere.

(2.) The image will be in the same position, but less than the object.

(3.) The image will be curved, but not spherical, like the mirror.

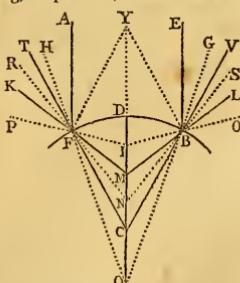

(4.) Parallel rays falling on this mirror, will have the image at half the distance of the centre from the mirror.

(5.) In converging rays, the distance of the object must be equal to half the distance of the centre, to make the image appear behind the mirror.

(6.) Diverging rays will have their image at less than half the distance of the centre.

III. In a Spherical Concave Mirror.

(1.) Parallel rays have their focus, or the image, at half the distance of the centre.

(2.) In the centre of the sphere the image appears of the same dimensions as the object.

(3.) Converging rays form an image before the mirror.

(4.) In diverging rays, if the object be at less than half the distance of the centre, the image will be behind the mirror, erect, curved, and magnified; but if the distance of the object be greater, the image will be before the mirror, inverted and diminished.

(5.) The solar rays, being parallel, will be collected in a focus at half the distance of its centre, where their heat will be augmented in proportion as the surface of the mirror exceeds that of the focal spot.

(6.) If a luminous body be placed in the focus of a concave mirror, its rays, being reflected in parallel lines, will strongly enlighten a space of the same dimensions with the mirror, at a great distance. If the luminous object be placed nearer than the focus, its rays will diverge, and so enlighten a larger space, but not so strongly. And on this principle it is that reverberators are constructed.

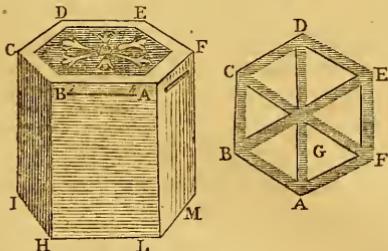

CATOPTRIC DIAL, a dial that exhibits objects by reflected rays. See *Reflecting Dial*.

CATOPTRIC Telescope, a telescope that exhibits objects by reflection. See *Reflecting Telescope*.

CATOPTRIC CISTULA, a machine, or apparatus, by which small bodies are represented extremely large, and near ones extremely wide, and diffused through a vast space; with other very pleasing phenomena, by means of mirrors, disposed by the laws of catoptrics in the concavity of a kind of chest.

There are various kinds of these machines, accommodated to the various intentions of the artificer: some multiply the objects, some magnify, some deform them, &c. The structure of one or two of them will suffice to show how many more may be made.

To make a Catoptric Cistula to represent several different scenes of objects, when viewed through different holes.

Provide a polygonal cistula, or box, like the multangular prism ABCDEF, and divide its cavity by diagonal planes AD, BE, CF, intersecting in the centre, into as many triangular cells as the chest has sides. Line those diagonal partitions with plain mirrors; and in the sides of the box make round holes, through which the eye may look within the cells of it. These holes are to be covered with plain glasses, ground within, but not polished, to prevent the objects in the cells from appearing too distinctly. In each cell are to be placed the different objects whose images are to be exhibited; then covering up the top of the chest with a thin transparent membrane, or parchment, to admit the light, the machine is complete.

For, from the laws of reflection, it follows, that the images of objects, placed within the angles of mirrors, are

multiplying, and appear some more remote than others; by which the objects in one cell will appear to take up more room than is contained in the whole box. Therefore by looking through one hole only, the objects in one cell will be seen, but those multiplied, and diffused through a space much larger than the whole box. Thus every hole will afford a new scene; and according to the different angles the mirrors make with each other, the representations will be different: if they be at an angle greater than a right one, the images will be monstrous, &c.

To make a *Catoptric Cistula* to represent the objects within it prodigiously multiplied, and diffused through a vast space.

Make a polygonous cistula or box, as before, but without dividing the inner cavity into any apartments, or cells; line the insides CBII, BHLa, ALMF, &c, with plane mirrors, and at the holes pare off the tin and quicksilver, that the eye may look through; place any object in the bottom MI, as a bird in a cage, &c.

Now by looking through the aperture hi, each object placed at the bottom will be seen vastly multiplied, and the images removed at equal distances from one another, like a great multitude of birds, or a large aviary.

CAVALIER, in Fortification, a mount of earth raised in a fortress higher than the other works, on which to place cannon, &c for scouring the field, or opposing a commanding work. Cavaliers are of different shapes; and are bordered with a parapet, to cover the cannon mounted upon them; their situation is also various, either in the curtain, the bastion, or the gorge. The cavalier is sometimes called a double bastion, and its use is to overlook the enemy's batteries, and to scour their trenches.

CAVALIERI (BONAVENTURA), a celebrated Italian mathematician of the 17th century. He was born at Milan in 1598, and became a friar of the order of the Jesuits of St. Jerome. Cavalieri was a disciple of Galileo, and the friend of Torricelli. He was professor of mathematics at Bologna: where several of his books were published, and where he died in the year 1647. His works that have been published, as far as I can discover, are as follow:

1. *DIRECTORIUM GENERALE URANOMETRICUM*; 4to, Bononia, 1632.—In this work the author treats of Trigonometry; and Logarithms, their construction, uses, and applications. The work includes also tables of logarithms of common numbers; with trigonometrical tables of natural sines, and logarithmic sines, tangents, secants and versed sines.

2. *Lo Specchio Ustorio overo Trattato delle Sezioni Coniche*: 4to, Bologna, 1632.—An ingenious treatise of conic sections.

3. *GEOMETRIA INDIVISIBILIBUS CONTINUORUM NOVA QUADAM RATIONE PROMOTA*: 4to, Bononia, 1635; and a 2d edition in 1653.—This is a curious original work in geometry, in which the author conceives the geometrical figures as resolved into their very small elements, or as made up of an infinite number of infinitely small parts, and on account of which he passes in Italy for the inventor of the infinitesimal calculus.

4. *TRIGONOMETRIA PLANA ET SPHERICA, LINEARIS, ET LOGARITHMICA*: 4to, Bononia, 1643.—A very neat and ingenious treatise on Trigonometry; with the tables of sines, tangents, and secants, both natural and logarithmic.

5. *EXERCITATIONES GEOMETRICAES SEX*: 4to, Bononia, 1647. This work contains Exercises on the method of Indivisi-

bles; Answers to the objections of Guldini; The use of Indivisibles in cossic powers or algebra, and in considerations concerning gravity; with a miscellaneous collection of problems.

CAVALLO (TIBERIUS), F. R. S. was born in the city of Naples the 30th of March 1749. His father, who was an eminent physician, died when Tiberius was scarcely 11 years of age. His relations continued to give him a liberal education; and as he was intended for a commercial life, with that view they sent him to England. He arrived in London in 1771, and continued in this country during the rest of his life. Hero his inclination led him to pursue scientific studies, the rudiments of which he had received at the university of Naples, and he attained to a considerable rank in several of the more fashionable and popular physical sciences. In March 1799, he was elected member of the Royal Academy of Sciences of Naples; and in December the same year he was elected home member of the Royal Society of London; where he died the 26th of December 1809, at 60 years of age.

Besides several ingenious papers inserted in the Philos. Trans., Mr. C. published separate and very interesting volumes on various popular and useful subjects: as, A Complete Treatise of Electricity in Theory and Practice, 1 vol. 8vo. 1777 (enlarged to 3 vols. in 1793).—An Essay on the Theory and Practice of Medical Electricity, 1 vol. 8vo. 1780.—A Treatise on the Nature and Properties of Air, and other Permanently Elastic Fluids, with an Introduction to Chemistry, 1 vol. 4to. 1781.—The History and Practice of Aerostation; 1 vol. 8vo. 1785.—Mineralogical Tables; folio, (accompanied with an 8vo explanatory pamphlet) 1785.—A Treatise on Magnetism, in Theory and Practice; 1 vol. 8vo. 1787.—Description and Use of the Telescopical mother-of-pearl Micrometer; 8vo. 1793.—An Essay on the Medicinal Properties of Factitious Airs, with an Appendix on the nature of Blood; 1 vol. 8vo. 1798, many of which have gone through several editions.

CAUDA Capricorni, a fixed star of the 4th magnitude, in the tail of Capricorn; called also by the Arabs, Dineb Algedi; and marked γ by Bayer.

CAUDA Ceti, a fixed star of the 3d magnitude; called also by the Arabs, Dineb Kactos; marked β by Bayer.

CAUDA Cygni, a fixed star of the 2d magnitude in the Swan's tail; called by the Arabs, Dineb Adigege, or Eldengiach; and marked α by Bayer.

CAUDA Delphini, a fixed star of the 3d magnitude, in the tail of the Dolphin; marked ϵ by Bayer.

CAUDA Draconis, or Dragon's tail, the moon's southern or descending node.

CAUDA Leonis, a fixed star of the first magnitude in the Lion's tail; called also by the Arabs, Dineb Eleced; and marked β by Bayer. It is called also Lucida Cauda.

CAUDA Ursæ Majoris, a fixed star of the 3d magnitude, in the tip of the Great Bear's tail; called also by the Arabs, Alalioth, and Benenath; and marked γ by Bayer.

CAUDA Ursæ Minoris, a fixed star of the 3d magnitude, at the end of the Lesser Bear's tail; called also the Pole Star, and by the Arabs, Alrukabah; and marked α by Bayer.

CAVENDISH (HENRY), F. R. S. son of the late Lord Charles Cavendish, was born Oct. 10, 1731, and died Feb. 24, 1810, consequently in his 79th year. Mr. C. lived and died a bachelor, devoting the whole hours and attentions of his long life most assiduously in cultivating the sciences, mathematical, physical, chemical, &c, in all

which he excelled in a very eminent degree. His genius and labours were rewarded with the most brilliant discoveries and improvements in the various branches of science; the records of which are chiefly to be found in the volumes of the Philos. Trans. He had studied, and rendered himself familiarly conversant with, every part of Newton's philosophy; the principles of which he applied, 40 years ago, to an investigation of the laws on which the phenomena of electricity depend. Pursuing the same research, on the occasion of the first experiments with the torpedo, he gave a satisfactory explanation of the remarkable powers of electrical fishes; pointing out that distinction between common and animal electricity, which has since been amply confirmed by the brilliant discoveries in Galvanism. Having very early turned his attention to pneumatic chemistry, in 1766 he ascertained the extreme levity of inflammable air, now called hydrogen gas; a discovery on which are founded many curious experiments, particularly that of aerial navigation. In the same line of science, he made the important discovery of the composition of water, by the union of two airs; which laid the foundation of the modern system of chemistry, which rests principally on this fact, and that of the decomposition of water, announced soon afterwards by M. Lavoisier.

As the purity of atmospherical air had been a subject of controversy, Mr. C. contrived essential improvements in the method of performing experiments with the audiometer; by means of which he was the first who showed, that the proportion of pure air, in the atmosphere, is nearly the same in all open places. The other, and much larger portion of our atmosphere, he sagaciously conjectured to be the basis of the acid of nitre; an opinion which he soon brought to the test, by an ingenious and laborious experiment, completely proving its truth; whence this air has now very generally obtained the name of nitrogen. So many and great discoveries spread his fame throughout Europe, and he was universally considered as one of the greatest philosophers of the age.

Among the labours of his latter days, was the nice and difficult experiment, by a mode and instrument contrived by the late Rev. John Michell, by which he determined the mean density of the earth, in a result not widely different from what was obtained in the more perfect way by the attraction of mountains. This density forms an element of consequence in delicate calculations of astronomy, as well as in geological inquiries. Even in the last year of his life, he proposed and described improvements in the manner of dividing large astronomical instruments, which promise very great advantages.

These pursuits, together with reading, of various kinds, by which he acquired a deep insight into almost every topic of general knowledge, formed the whole occupation of his life, and indeed constituted his sole amusement. The love of truth alone was sufficient to fill his mind. From his attachment to such occupations, and the constant resource he found in them, together with a shyness and diffidence natural to his disposition, his habits had, from early life, been secluded. His manners were mild—his mind firm—his nature benevolent and complacent. He was liberal, without being profuse; and charitable, without ostentation.

CAVETTO, a hollow member or moulding, containing a quadrant of a circle, and having an effect just contrary to that of a quarter round. It is used as an ornament in cornices.

CAULICOLES, Cauliculi, in Architecture, are those 8 lesser branches or stalks in the Corinthian capital, which spring out from the four greater principal caules or stalks.

CAUSE, Physical, that which produces a sensible corporeal effect. Thus, the sun is a physical cause of light. Others define a physical cause to be that which produces its effects by a physical virtue, or natural influence.

CAUSTIC CURVE, in the higher geometry, is a curve formed by the concourse or coincidence of the rays of light, when either reflected, or refracted, from some other curve.

Every curve therefore has its twofold caustic: accordingly, caustics are divided into catacaustics, and diacaustics; the one formed by reflection, the angle of reflection being equal to that of incidence; the other by refraction. See the two articles **CATACAUSTICS** and **DIACAUSTICS**.

To pursue the doctrine of caustics, as it relates to optics, consult Häuy's Philosophy, vol. 2; and as a branch of the doctrine of curves, consult the writers on fluxions, as Hays, or Hodgson, or Stone, &c.

CAZEMATE. See **CASEMATE**.

CAZERN. See **CASERN**.

CEGINUS, a fixed star of the 3d magnitude, in the left shoulder of Bootes; and marked γ by Bayer.

CELERITY, is the velocity or swiftness of a body in motion; or that affection of a body in motion by which it can pass over a certain space in a certain time.

CELESTIAL GLOBE, &c. See **GLOBE, &c.**

CELLARIUS (CHRISTOPHER), a learned geographer and historiographer of the 17th century. He was born in 1638, at Simalcalde in Franconia, where his father was minister. Our author was successively rector of the colleges at Weimar, Zeits, and Mersbourg, and professor of eloquence and history in the university founded by the king of Prussia at Hall in 1693, where he composed the greatest part of his works.

His great application to study hastened the infirmities of old age; for it has been said, he would spend whole days and nights together over his books, without any attention to his health, or even the calls of nature. He died in 1707, at 69 years of age.

Cellarius was author of a great number of books, on various subjects; but those for which he has a place here, are his geographical works, which are as follow:

1. *Notitia Orbis Antiqui*, 2 vols, in 4to; and is esteemed the best work extant on the ancient geography.

2. *Atlas Cœlestis*; in folio.

3. *Historia Antiqua*, 2 vols, in 12mo; being an abridgment of universal history.

CENTAURUS, the *Centaur*, one of the 48 old constellations, being a southern one, and is in form half man and half horse. It is fabled by the Greeks that it was Chiron the Centaur, who was the tutor of Achilles and Esculapius. The stars of this constellation are, in Ptolemy's catalogue 37, in Tycho's 4, and in the Britannic catalogue, with Sharpe's appendix, 35.

CENTER, and CENTERING. See **CENTRE, and CENTRING**.

CENTESM, the 100th part of any thing.

CENTIGRADE, the division into grades or degrees by hundredth parts, called also Centesimal, contracted into Centemes, or still more contracted Cents.

The North-American states have their money (dollars), divided into hundredth parts or cents. And the French nation have lately divided all their money, weights, and

Vol. I.

measures, decimaly; which is allowed to be the best way. They have even divided the circular quadrant into cents, for trigonometrical uses, on the centigrade way, having 100 in the quadrant, while we have 90: therefore the magnitude of their degree, is to that of ours, as 9 to 10; but the number of their degrees to the number of ours, as 10 to 9: hence, to change French degrees into English, diminish them by one-tenth, or multiply them by 9, and cut off one figure for a decimal: and to find the number of French degrees answering to a given number of English, annex a cipher to the letter, then divide them by 9.

The French have also their centigrade thermometer, &c. In that instrument they divide the distance between the freezing and boiling points into 100, which we divide into 180; therefore the length of their thermometrical degree, is to the length of ours, as 180 to 100, or as 18 to 10, or 9 to 5; and the number of theirs to the number of ours, as 10 to 18, or 5 to 9; therefore, to change French thermometer degrees into English, multiply the former by 9, and divide by 5: so, to find the English degrees answering to 15 French, the 5th of 15 is 3, then $3 \times 9 = 27$ are the English degrees answering to 15 French: but as the French freezing point is at 0, and ours at 32, therefore $27 + 32 = 59$ is the point or degree on the English thermometer, answering to that of 15 on the French.

CENTRAL, something relating to a centre. Thus we say central eclipse, central forces, central rule, &c.

CENTRAL Eclipse, is when the centres of the luminaries exactly coincide, and fall directly in a line with the eye.

CENTRAL Forces, are forces having a tendency directly towards or from some point or centre; or forces which cause a moving body to tend towards, or recede from, the centre of motion. And accordingly they are divided into two kinds, in respect to their different relations to the centre, and hence are called centripetal, and centrifugal.

The doctrine of central forces constitutes a considerable branch of the Newtonian philosophy, and has been greatly cultivated by mathematicians, on account of its extensive use in the theory of gravity, and other branches of physico-mathematical science.

In this doctrine, it is supposed that matter is equally indifferent to motion or rest, or rather that it always resists any attempt to change its state; or that a body at rest never moves itself, and that a body in motion never of itself changes either the velocity or the direction of its motion; but that every motion would continue uniformly, and its direction rectilinear, unless some external force or resistance affected it or should act upon it. Hence, when a body at rest always tends to move, or when the velocity of any rectilinear motion is continually accelerated or retarded, or when the direction of a motion is continually changed, and a curve line is thereby described, it is supposed that these circumstances proceed from the influence of some power that acts incessantly; which power may be measured, in the first case, by the pressure of the quiescent body against the obstacle which prevents it from moving, or by the velocity gained or lost in the second case, or by the flexure of the curve described in the 3d case; due regard being had to the time in which these effects are produced, and other circumstances, according to the principles of mechanics. Now the power or force of gravity produces effects of each of these kinds, which fall under our constant observation near the surface of the earth; for the same power which renders bodies heavy,

while they are at rest, accelerates their motion when they descend perpendicularly; or retards them when they ascend; and bends the track of their motion into a curve line, when they are projected in a direction oblique to that of their gravity. But we can judge of the forces or powers that act on the celestial bodies by effects of the last kind only. And hence it is, that the doctrine of central forces is of so much use in the theory of the planetary motions.

Sir I. Newton has treated of central forces in lib. 1, sec. 2, of his Principia, and has demonstrated this fundamental theorem of central forces, viz., that the areas which revolving bodies describe by radii drawn to an immovable centre, lie in the same immovable planes, and are proportional to the times in which they are described. Prop. 1.

It is remarked by a late eminent mathematician, that this law, which was originally observed by Kepler, is the only general principle in the doctrine of centripetal forces; but since this law, as Newton himself has proved, cannot hold in cases where a body has a tendency to any other than one and the same point, there seems to be wanting some law that may serve to explain the motions of the moon and satellites which gravitate towards two different centres: the law he lays down for this purpose is, that when a body is urged by two forces tending constantly to two fixed points, it will describe, by lines drawn from the two fixed points, equal solids in equal times, about the line joining those fixed points. See Machin, on the Laws of the Moon's Motion, in the Postscript. This short treatise is published at the end of the English translation of Sir Isaac Newton's Principia. See also a demonstration of this law by Mr. William Jones, in the Philos. Trans. vol. 59. Very learned tracts have also been since given, when the motion respects, not two only, but several centres, by many ingenious authors, and practical rules deduced from them for computing the places &c of planets and satellites; as by Lagrange, Laplace, Waring, &c, &c. See Berlin Memoirs; those of the Academy of Sciences at Paris; and the Philos. Trans. of London.

M. Demoivre gave elegant general theorems relating to central forces, in the Philos. Trans. and in his Miscel. Analyt. 231.—Let $m\bar{p}q$ be any given curve, in which a body moves: let P be the place of the body at any time; s the centre of force, or the point to which the central force acting on the body is always directed; ps the radius of curvature at the point P ; and st perpendicular to the tangent PT ; then will the centripetal force be every where proportional to the quantity $\frac{sp}{GP \times ST^2}$. Vid. ut supra.

M. Varignon has also given two general theorems on this subject in the Memoirs of the Acad. an. 1700, 1701; and has shown their application to the motions of the planets. See also the same Memoirs, an. 1706, 1710.

Mr. Maclaurin has also treated the subject of central forces very ably and fully, in his Treatise on Fluxions, art. 416 to 493; where he gives a great variety of expressions for these forces, and several elegant methods of investigating them.

Laws of CENTRAL FORCES.

1. The following is a very clear and comprehensive rule, for which we are obliged to the Marquis de l'Hôpital:

Suppose a body of any determinate weight to revolve uniformly about a centre, with any given velocity; find from what height it must have fallen, by the force of gravity, to acquire that velocity; then, as the radius of the circle it describes, is to double that height, so is its weight to its centrifugal force. So that, if b be the body, or its weight or quantity of matter, v its velocity, and r the radius of the circle described, also $g = 16\frac{1}{2}$ feet; then, by the laws of falling bodies we have $4g^2 : v^2 :: g : \frac{v^2}{4g}$, the height due to the velocity v ; and by rule $r : \frac{v^2}{2g} :: b : \frac{v^2}{2gr} = f$ the centrifugal force. Hence, if the centrifugal force be equal to the gravity, the velocity is equal to that acquired by falling through half the radius.

2. The central force of a body moving in the periphery of a circle, is as the versed sine AM of the indefinitely small arc AE ; or it is as the square of that arc AE directly, and as the diameter AB inversely. For AM is the space through which the body is drawn from the tangent in the given time, and $2AM$ is the proper measure of the intensity of the central force. But, AE being very small, and therefore nearly equal to its chord, we shall have by the nature of the circle

$$AB : AE :: AE : AM = \frac{AE^2}{AB}.$$

3. If two bodies revolve uniformly in different circles; their central forces are in the duplicate ratio of their velocities directly, and the diameters or radii of the circles inversely; that is, $F : f :: \frac{v^2}{d} : \frac{v^2}{D} :: \frac{v^2}{R} : \frac{v^2}{r}$.

For the force, by the last article, is as $\frac{AE^2}{AB}$ or $\frac{AE^2}{d^2}$; and the velocity v is as the space AE uniformly described.

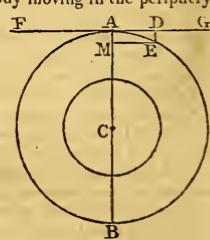

4. And hence, if the radii or diameters be reciprocally in the duplicate ratio of the velocities, the central forces will be reciprocally in the duplicate ratio of the radii, or directly as the 4th power of the velocities; that is, if $v^2 : v^2 :: r : R$, then $F : f :: v^3 : R^2 :: v^4 : v^2$.

5. The central forces are as the diameters of the circles directly, and squares of the periodic times inversely. For if c be the circumference described in the time t , with the velocity v ; then the space $c = vt$, or $v = \frac{c}{t}$; hence, using this value of v in the 3d rule, it becomes

$F : f :: \frac{c^2}{dt^2} : \frac{c^2}{dr^2} :: \frac{d}{t^2} : \frac{d}{r^2} :: \frac{R}{t^2} : \frac{r}{t^2}$; since the diameter is as the circumference.

6. If two bodies, revolving in different circles, be acted on by the same central force; the periodic times are in the subduplicate ratio of the diameters or radii of the circles; for when $F = f$, then $\frac{d}{t^2} = \frac{d}{P^2}$, and $d : d :: t^2 : t^2$, or $t : t :: \sqrt{d} : \sqrt{d} :: \sqrt{r} : \sqrt{r}$.

7. If the velocities be reciprocally as the distances from the centre, the central forces will be reciprocally as the cubes of the same distances, or directly as the cubes of the velocities. That is, if $v : v' : r : R$, then is $F : f :: v^3 : R^3 :: v^3 : v'^3$. For $v : f :: \frac{v^2}{n} : \frac{v^2}{r} :: \frac{r^2}{n} : \frac{R^2}{r} :: r^3 : R^3 :: v^3 : v'^3$.

8. If the velocities be reciprocally in the subduplicate ratio of the central distances, the squares of the times will be as the cubes of the distances: thus, if $v^2 : v^2 : r : R$, then is $T^2 : t^2 : r^3 : R^2$. For by 3d and 5th $\frac{v^2}{R} : \frac{v^2}{r} : \frac{r}{R} : \frac{r^2}{t^2}$, and $\frac{v^2 \times r}{v^2 \times R} = \frac{r^2}{R^2}$ (by this) $= \frac{r \times t^2}{r \times T^2}$, and hence $T^2 : t^2 : r^3 : R^2$.

9. Therefore, if the forces be reciprocally as the squares of the central distances, the squares of the periodic times will be as the cubes of the distances; or when $F : f :: r^2 : R^2$, then is $T^2 : t^2 : r^3 : R^2$. For by 5th, $F : f :: \frac{R}{r^2} : \frac{r^2}{t^2}$, and by this $F : f :: r^2 : R^2$, thereof, $\frac{R}{r^2} : \frac{r^2}{t^2} :: r^2 : R^2$, and hence $T^2 : t^2 : r^3 : R^2$.
